all τ	0.853	0.974	0.984

elasticities of substitution tend to be more negative than before (reflecting the concavity restriction), while imposing concavity alone was enough to make the average over all replications of each partial elasticity of substitution turn out to be positive. Expenditure and compensated price elasticities calculated using $\bar{\theta}$ are shown in table 3, part B, while table 4, part B contains corresponding uncompensated elasticities.

The system was less consistent with the restriction that all meats are substitutes. Imposing concavity and substitutability jointly reduces the parameter space D further; the probability that the joint restriction holds, given diffuse prior beliefs, falls to 0.16. (Alternatively, this can be viewed as a conditional probability of substitutability, given that concavity is imposed, of $0.16/0.57 = 0.28$.) This relatively stronger rejection of prior beliefs casts some doubt on the estimated system being a valid representation of preferences. Nonetheless, posterior means were calculated for the remaining elasticities. These numbers are shown in table 2 for the substitution elasticities and in part C of tables 3 and 4 for the price elasticities. For comparison to the results in table 1, the constrained parameter estimates are reported in table 6.

It is important to note that violations of the substitution restriction are not due solely to the cases of complementarity relationships implied by $\hat{\theta}$ —beef and fish or pork and fish. Any elasticity could be responsible. Unless the posterior density for any particular elasticity of substitution implies that it is positive with probability one, each can be responsible for any particular replication violating the constraint. We examined the posterior distributions for each elasticity and found that those two elasticities indeed were responsible for the lion's share of rejections. We never observed a replication that implied that beef and pork were complements at the mean budget shares, while the estimated probabilities that the substitution elasticity was positive for the beef-poultry and pork-poultry combinations were both greater than 0.99. In contrast, the probability that the elasticity of substitution was positive for the remaining cases of $\sigma_{\text{beef} \cdot \text{fish}}$, $\sigma_{\text{pork} \cdot \text{fish}}$, and $\sigma_{\text{poultry} \cdot \text{fish}}$ were 0.59, 0.63, and 0.89, respectively, suggesting that fish is most responsible for the violations.

One can also reexamine the trend results with an inequality-constrained model; although the trend coefficients do not affect elasticities directly, their point estimates are correlated with those of the γ_{ij} parameters and will be affected by imposing the inequality restrictions. The

^a The numerical standard errors for each element of $\bar{\theta}$ are reported in square brackets, and the corresponding standard deviations are in parentheses. Parameters without these measures were obtained from the equality restrictions, as in table 1.

negative point estimates for beef and pork that were reported in table 1 for the trend effects observed without the inequality restrictions are less than the resulting posterior mean values for those two coefficients. The trend coefficients in both the beef and pork equations rise in absolute value, as does the implied one in the omitted fish equation, when concavity and then substitutability are imposed. At the same time, the coefficient in the poultry equation falls slightly. All of the estimated means of the posterior distributions for the trend coefficients are more than twice the corresponding standard deviations, as shown in table 6, although this is barely true for poultry. The posterior probability of a negative value in the beef and pork equations was 1, which was the probability of a positive value in the fish equation; only for poultry does the posterior distribution have some probability on both sides of zero, although that value is small for negative values, as the estimated probability of a positive value in the poultry equation is over .95.

A sample size of 10,000 was sufficiently large to obtain accurate estimates for these expectations from the posterior distribution. This is reflected in the small numerical standard error estimates, obtained as described in step (f). These are well within tolerable ranges for applications.

Summary and Conclusions

An unfortunate byproduct of the use of demand systems that do not restrict substitution elasticities is that theoretical restrictions such as symmetry or homogeneity are often violated. More difficult to cope with are inequality restrictions. The familiar problem of curvature or monotonicity restrictions is the best example, but the signs of elasticities of substitution between goods are also good examples. In order to determine whether an estimated demand system is entirely consistent with prior beliefs, it is important to be able to impose or make inferences about inequality restrictions.

We showed that a Bayesian procedure handled this problem nicely. It produces constrained parameter estimates and also an estimate of the probability that the restrictions are true. For the demands for beef, pork, chicken, and fish in Canada, some support was found for the concavity of the consumer's expenditure function underlying an almost ideal demand system ($p = 0.57$), while the monotonicity restric-

tion is definitely consistent with the model ($p = 1$). On the other hand, the sample information is less consistent with prior beliefs about substitution relationships; it reveals a low conditional probability (given concavity) that these four goods are all substitutes for each other ($p = .28$). Finally, whether or not these restrictions are imposed, the almost ideal demand system implies a negative trend affecting beef and pork consumption and a positive trend for chicken and fish.

Because the necessary integrals over the exact posterior density were quite complicated, Monte Carlo integration was used to estimate parameter values. The p.d.f. of the exact posterior was known but not recognizable, which made sampling from it difficult. This problem was overcome by importance sampling.

These findings concerning Canadian meat demand are conditional on the observed data and on the specification of the almost ideal demand system. All such inferences in demand systems are also conditional on separability and aggregation assumptions (Chalfant and Alston); but, if these assumptions are valid, the results must be interpreted as questioning either the prior belief that these goods are substitutes or the functional form for the demand system. If one is satisfied with the almost ideal model and unconcerned about the substitution restriction, the reasonably good results for concavity permit the use of the constrained elasticity estimates for policy analysis. The ability to produce a theoretically consistent set of elasticities is one of the main advantages of this procedure.

On the other hand, one might hesitate to use the estimated trends as evidence concerning taste changes if the lower probability for the restriction that all meats are substitutes is a cause for alarm. However, the results suggest that the almost ideal model cannot be estimated without the trend effects. Further research with other functional forms can help to address this question. It will be of interest to see how the probabilities we report change when another functional form is tried; Alston and Chalfant and the Monte Carlo studies to date certainly offer evidence that point estimates can change. In that light, the procedure and restrictions suggested in this study serve not only as a means to interpret the data but as a way of evaluating alternative functional forms for demand systems.

Ex Post Flexibility and Choice of Capacity for Loss Reduction

L. Dean Hiebert

This paper examines the implications of *ex post* utilization flexibility for the firm's *ex ante* choice of capacity to supply a loss-reducing input. It is shown that the optimal *ex ante* choice is greater in the presence of flexibility than in the absence of flexibility. It is also shown that the total effect of an increase in risk on the *ex ante* choice includes a flexibility effect when *ex post* flexibility is present. The flexibility effect always tends to increase the demand for capacity.

Key words: damage control, *ex post* flexibility, loss reduction.

The firm's use of loss-reducing inputs has been widely studied. Feder analyzes the use of pesticides to reduce crop losses. Centner and Wetzstein consider the use of disease control measures by the buyers of livestock. Hiebert (1983) examines a firm's demand for self-insurance, an input which reduces the severity of the loss resulting from randomly occurring accidents. Lichtenberg and Zilberman discuss the specification of the production function when loss-reducing inputs are used.

This previous literature assumes that all loss containment decisions must be made before learning the actual severity of the realized state of nature. In certain decision-making contexts, however, some loss reduction decisions can be postponed until the realized state of nature is known to the decision maker. Suppose a firm must select a capacity to supply a loss-reducing input before learning the actual state of nature but can select the utilization of this capacity after learning the actual state of nature. In this case capacity is an *ex ante* decision variable, while the utilization of this capacity is an *ex post* decision variable.¹ For example, wind machines and sprinklers in citrus groves represent a capacity to supply frost protection services, but the

utilization of this capacity is chosen after the actual state of nature can be accurately predicted.

This paper considers the effect of *ex post* utilization flexibility on a firm's *ex ante* commitment to loss reduction. The firm makes an *ex ante* commitment by choosing a capacity to supply the loss-reducing input. If *ex post* utilization flexibility is present, the firm postpones the input choice until after learning the realized state of nature. In the absence of *ex post* utilization flexibility, the use of the input is fixed and equal to the capacity level. It is shown that the introduction of *ex post* flexibility always increases a firm's *ex ante* commitment to loss reduction. Moreover, the introduction of *ex post* flexibility can reverse the direction of the firm's *ex ante* capacity response to an increase in uncertainty.

Capacity Choice with Ex Post Flexibility

This section develops a simple model of capacity choice when *ex post* utilization flexibility is present. The firm selects a capacity level, k , before learning the actual realization of the state of nature. After observing the realized state of nature, the firm chooses the quantity of loss reduction services, x , given the capacity constraint $x \leq k$.

If a disaster occurs, the dollar loss is given by the damage function

$$(1) \quad D(x, \theta) \quad \text{for } x \leq k,$$

where θ is a random variable which represents the severity of the state of nature. The loss is an increasing function of θ . For all values of θ ,

L. Dean Hiebert is an associate professor of economics, Illinois State University.

The author thanks two anonymous reviewers for helpful comments.

¹ Turnovsky, Hartman, and Epstein discuss the *ex ante* and *ex post* decisions of a competitive firm facing product price uncertainty. Robison and Barry (chap. 17) consider a situation in which a "flexibility" characteristic of a durable is chosen before the selling price of the durable's services is known, while the quantity of services to be extracted can be chosen after learning the price.

the loss is a decreasing strictly convex function of x ($D_x < 0$, $D_{xx} > 0$), implying that loss reduction measures are subject to diminishing returns. The marginal effectiveness of the input will depend, in general, on the realized state of nature. Two alternatives are considered. In one case, the marginal effectiveness of the input is greater in more adverse states of nature ($-D_{x\theta} > 0$).² In the other case, the marginal effectiveness of the input is greater in more benign states of nature ($-D_{x\theta} < 0$).

Consider first the firm's *ex post* decision. Let $w(x)$ represent the variable cost of utilizing the installed capacity, where variable cost is an increasing convex function of x . The firm will choose x so that the marginal return to the input is greater than or equal to the marginal cost of the input. Thus, the optimal level of the input, x^* , must satisfy

$$(2) \quad -D_x(x^*, \theta) \geq w'(x^*) \quad \text{for } x^* \leq k.$$

Suppose that loss reduction measures are more effective in more severe states of nature. Then the optimal value of x is an increasing function of θ . If the state of nature is sufficiently severe, the strict inequality will hold in (2) and capacity is fully utilized, $x^* = k$. In less severe states of nature, the equality will hold in (2), and $x^* \leq k$. Hence, the optimal value of x can be written as

$$(3) \quad x^* = \min [x^*(\theta, w), k],$$

where $x^*(\theta, w)$ is the value of x which satisfies $-D_x(x^*, \theta) = w'(x^*)$.

At the time the firm makes the capacity decision, θ and hence x^* are unknown. The firm is risk averse and chooses a level of capacity to maximize the expected utility of *ex post* profit.³ Expected utility in any period can be written as

$$(4) \quad EU = (1-p)U(W-rk) + p \int_0^{\theta^*(k)} U(W-D(x^*, \theta)) - w(x^*) - rk dF$$

² In this case x is a risk-reducing input (as defined by Just and Pope) because the variance of profit is a decreasing function of x . Alternatively, if $-D_{x\theta} < 0$, the input is a risk-increasing input. In Hartman and Epstein, the inputs are risk-increasing because product price enters the profit function multiplicatively.

³ If the profit endowment and the price variables are identical in all periods and if θ is identically and independently distributed in all periods, then maximizing the present value of expected utility is identical to maximizing equation (4).

$$- p \int_{\theta^*(k)}^{\infty} U(W-D(k, \theta)) - w(k) - rk dF,$$

where U is a strictly concave utility function, W denotes the firm's profit endowment which is subject to the risk of partial loss D , r is the fixed cost of a unit of capacity, p is the probability that a loss occurs, and F is the distribution function of θ . Both W and r are assumed to be non-random constants; $\theta^*(k)$ denotes the critical value of θ for which the full utilization of capacity is the unconstrained *ex post* optimum. It is defined by $-D_x(k, \theta^*) = w$ and is a continuous function of the level of capacity.

The optimal level of capacity must satisfy the condition⁴

$$(5) \quad \partial EU / \partial k = (1-p)U'(\pi_0) \cdot -r - p \int_0^{\infty} U'(\pi_1) \cdot -rdF + p \int_{\theta^*(k)}^{\infty} U'(\pi_1)(-D_x(k, \theta) - w'(k))dF = 0,$$

where π_0 denotes profit if no loss occurs and π_1 denotes (random) profit if a loss actually occurs. This condition indicates that capacity is expanded until the marginal benefit (in expected utility) of increased capacity equals the marginal cost of capacity. The expectation of the marginal benefit is over those states of nature in which capacity is fully utilized because the benefit of added capacity is zero otherwise.

Alternatively, consider the case in which loss reduction is more effective in more benign states of nature. In this case the optimal input level is a decreasing function of θ . If the state of nature is sufficiently benign, the strict inequality will hold in (2) and $x^* = k$. In more severe states of nature the equality will hold and $x^* \leq k$. The firm's expected utility can be written as

$$(6) \quad EU = (1-p)U(W-rk) + p \int_0^{\theta^*(k)} U(W-D(k, \theta)) - w(k) - rk dF + p \int_{\theta^*(k)}^{\infty} U(W-D(x^*, \theta) - w(x^*) - rk) dF.$$

⁴ Condition (5) is also a sufficient condition for an optimum because EU is a strictly concave function of k .

The optimal level of capacity now satisfies

$$(7) \quad \partial EU / \partial k = (1 - p)U'(\pi_0) \cdot -r \\ + p \int_0^\infty U'(\pi_1) \cdot -rdF \\ + p \int_0^{\theta^*(k)} U'(\pi_1)(-D_x(k, \theta) \\ - w'(k))dF = 0.$$

Capacity Choice with Fixed Utilization

If the firm's use of x cannot be varied *ex post*,⁵ then $x = k$, and expected profit becomes

$$(8) \quad EU = (1 - p)U(W - rk) + p \int_0^\infty \\ \cdot U(W - D(k, \theta) - w(k) - rk)dF.$$

The optimal level of capacity must satisfy the condition

$$(9) \quad \partial E\pi / \partial k = (1 - p)U'(\pi_0) \cdot -r \\ + p \int_0^\infty U'(\pi_1) \cdot -rdF \\ + p \int_0^\infty U'(\pi_1)(-D_x(k, \theta) \\ - w'(k))dF = 0.$$

Again, the marginal benefit of added capacity is equated to its marginal cost. The expectation of the marginal benefit is over all states of nature because the firm is unable to vary the utilization of capacity *ex post*. In this case the *ex post* marginal net return to the loss reducing input, $-D_x(k, \theta) - w'(k)$, will be negative in some states of nature. This immediately implies that the optimal value of expected utility is greater in the presence of flexibility than in the absence of flexibility.

The Impact of Flexibility

This section compares the optimal choice when flexibility is present with that when flexibility is absent.

Suppose that loss reduction measures are more effective in more severe states of nature. Subtracting the left-hand side of condition (9) from the left-hand side of condition (5) and evaluating the result at the optimal choice under zero flexibility yields

$$(10) \quad -p \int_0^{\theta^*(k)} U'(\pi_1)(-D_x(k, \theta) - w'(k))dF > 0$$

because $-D_{x\theta} > 0$. This result implies that the firm selects a larger capacity in the presence of flexibility than in the absence of flexibility. It is because flexibility increases the marginal benefit of additional capacity.⁶

A similar result is obtained when loss reduction is more effective in less severe states of nature. Subtracting the left-hand side of (9) from the left-hand side of (7) yields

$$(11) \quad -p \int_{\theta^*(k)}^\infty U'(\pi_1)(-D_x(k, \theta) - w'(k))dF > 0$$

because $-D_{x\theta} < 0$. Again, the presence of flexibility increases the firm's demand for loss-reducing capacity. Hence, the impact of *ex post* flexibility on the optimal capacity choice does not depend on the risk-affecting character of the technology.

The Impact of Increased Uncertainty

This section considers the impact on the optimal capacity choice of increases in uncertainty as defined by Rothschild and Stiglitz.⁷ It is shown that the introduction of *ex post* flexibility can reverse the direction of the firm's response to an increase in uncertainty.⁸

Denote the cumulative distribution function of θ by $F(\theta, s)$, where s is a parameter representing the dispersion of the distribution. An increase in s represents a mean-preserving spread of the distribution if the following conditions are met:

⁶ This result is not the result of risk aversion. A risk-neutral firm would also select a larger capacity when flexibility is present.

⁷ It is easy to show that an increase in uncertainty reduces expected utility if D is a convex function of θ ($D_{\theta\theta} \geq 0$).

⁸ When *ex post* flexibility is present, an increase in risk aversion increases the optimal capacity if the input is risk reducing ($-D_{x\theta} > 0$). However, if the input is risk increasing ($-D_{x\theta} < 0$), then the effect of increased risk aversion is indeterminate. These results conform exactly to those obtained when *ex post* flexibility is absent (see Hiebert 1989).

⁵ An example is fire retardant material installed in the walls of a building.

$$(12) \quad \int_0^{\infty} F_s(\theta, s) d\theta = 0, \quad \text{and}$$

$$(13) \quad T(y, s) = \int_0^y F_s(\theta, s) d\theta \geq 0 \quad \text{for all } y.$$

The effect of an increase in uncertainty is given by

$$(14) \quad \partial k^* / \partial s = -(\partial^2 EU / \partial k \partial s) / (\partial^2 EU / \partial k^2).$$

Because the second-order conditions imply that the denominator is negative, the sign of (14) is the same as the sign of $\partial^2 EU / \partial k \partial s$.

First, consider the case where no flexibility is present. Differentiating (9) with respect to s gives

$$(15) \quad \partial^2 EU / \partial k \partial s = p \int_0^{\infty} U'(\pi_1)(-D_x(k, \theta) - w'(k) - r) dF_s(\theta, s).$$

Integrating the right-hand side of (15) twice by parts yields

$$(16) \quad \partial^2 EU / \partial k \partial s = p \int_0^{\infty} \partial^2 (U'(\pi_1)(-D_x(k, \theta) - w'(k) - r)) / \partial \theta^2 T d\theta$$

because $F_s(0, s) = F_s(\infty, s) = T(0, s) = T(\infty, s) = 0$. A condition sufficient to determine the effect of increased uncertainty is that $\partial^2 (U'(\pi_1)(-D_x - w' - r)) / \partial \theta^2$ be uniformly positive or negative. If $U'(\pi_1)(-D_x - w' - r)$ is a strictly convex (concave) function of θ , then the firm responds to an increase in uncertainty by increasing (decreasing) the optimal level of capacity.⁹ These conditions are the familiar Rothschild-Stiglitz conditions for signing the effect of a mean-preserving increase in uncertainty.

However, if *ex post* flexibility is present, the Rothschild-Stiglitz conditions are no longer sufficient to determine the firm's response to an increase in uncertainty. Suppose x is more effective in more severe states. Differentiating the first-order condition (5) with respect to s and integrating by parts twice gives

$$(17) \quad \begin{aligned} \partial^2 EU / \partial x \partial s = & p U'(\pi_1(\theta^*)) (-D_{x\theta}(k, \theta^*)) \\ & \cdot T(\theta^*, s) + p \int_0^{\infty} \partial^2 (U'(\pi_1) \cdot (-r)) / \partial \theta^2 T d\theta \\ & + p \int_{\theta^*}^{\infty} \partial^2 (U'(\pi_1)(-D_x(k, \theta) - w'(k))) / \partial \theta^2 T d\theta, \end{aligned}$$

where $\pi_1(\theta^*)$ denotes profit evaluated at θ^* . The second and third terms in (17) are analogous to (16). The first term in (17) arises only when *ex post* flexibility is present and can be called a flexibility effect.¹⁰ Since $-D_{x\theta} > 0$, this effect is always positive and thus tends to increase the firm's optimal capacity commitment in the face of increased uncertainty.

If $U'(\pi_1)(-D_x - w' - r)$ is a concave function of θ , then (16) and (17) can clearly have opposing signs. Hence, it is possible that an increase in uncertainty will cause a firm to enlarge its capacity commitment if *ex post* flexibility is present but not if such flexibility is absent.

The result is similar if x is more productive in less severe states. Differentiating (7) with respect to s and integrating two times by parts yields

$$(18) \quad \begin{aligned} \partial^2 EU / \partial x \partial s = & -p U'(\pi_1(\theta^*)) (-D_{x\theta}(k, \theta^*)) \\ & \cdot T(\theta^*, s) + p \int_0^{\infty} \partial^2 (U'(\pi_1) \cdot (-r)) / \partial \theta^2 T d\theta \\ & + p \int_0^{\theta^*} \partial^2 (U'(\pi_1)(-D_x(k, \theta) - w'(k))) / \partial \theta^2 T d\theta. \end{aligned}$$

The first term is the flexibility effect, which again is positive since $-D_{x\theta} < 0$. Hence, the presence of a positive flexibility term does not depend on the risk-affecting character of the technology. As in the previous case, the introduction of utilization flexibility can reverse the direction of the firm's *ex ante* response to an increase in uncertainty.

An Example

The following example illustrates the results of this paper.

⁹ If the firm is risk neutral, the comparative static results depend on whether $-D_x$ is convex or concave in θ . As a special case, if the firm is risk neutral and θ enters the loss function multiplicatively, then the capacity decision of the firm is unaffected by an increase in risk.

¹⁰ A flexibility effect does not arise in the models of *ex post* choice used by Turnovsky, Hartman, Epstein, and Robison and Barry. Hence, in these models, the Rothschild-Stiglitz conditions are sufficient to determine the impact of an increase in uncertainty.

(a) There are only three possible loss states of the world: $\theta \in \{1/4, 1, 7/4\}$ with probabilities $\alpha/2, 1 - \alpha, \alpha/2$. An increase in α corresponds to a mean-preserving spread of this distribution of θ .

(b) The damage function is given by $(D_0 - 2\sqrt{x})\theta$. For this specification, $-D_x = \theta/\sqrt{x}$ and $-D_{x\theta} = 1/\sqrt{x} > 0$.

(c) The marginal cost of utilizing capacity is a constant, w .

(d) The firm is risk neutral.

When there is no *ex post* flexibility, the first-order condition for optimal capacity choice is

$$\partial E\pi/\partial k = -r - w + p/\sqrt{k} = 0.$$

Let $r = 1/10$, $w = 1/2$, and $p = 6/10$. Then the optimal capacity choice is 1. [Observe that the *ex post* marginal net return to the input $(-D_x - w)$ is negative if the realized value of θ is $1/4$].

On the other hand, when *ex post* flexibility is present, optimal capacity choice is determined by

$$\begin{aligned} \partial E\pi/\partial k &= -r + p(1 - \alpha)(1/\sqrt{k} - w) \\ &+ p(\alpha/2)(7/4\sqrt{k} - w) = 0. \end{aligned}$$

For $\alpha = 1/3$, it can be verified that the optimal capacity choice is $23/14$.

Now let $\alpha = 1/2$. When *ex post* flexibility is absent, the optimal capacity choice is unaffected by a mean-preserving increase in uncertainty. However, when *ex post* flexibility is present, the optimal capacity is $45/26 > 23/14$. An increase in uncertainty increases the demand for capacity.¹¹ The introduction of *ex post* flexibility qualitatively alters the firm's response to an increase in uncertainty.

Conclusions

The existing literature has assumed that all damage control decisions must be made *ex ante*. This

paper has examined the implications of *ex post* utilization flexibility for the firm's choice of capacity to supply a loss-reducing input. It was shown that the optimal capacity is always greater when utilization is flexible rather than fixed. In addition, the total effect of increased uncertainty on the optimal choice includes a flexibility effect when *ex post* flexibility is present. This flexibility effect always tends to increase the optimal capacity.

The Application and Economic Interpretation of Selectivity Models

Chung L. Huang, Robert Raunikaar, and Sukant Misra

Substantial differences in economic interpretations may be inferred from the estimated selectivity model results. Using the demand for frozen concentrated orange juice (FCOJ) as an example, the study suggests that the consumption patterns are quite similar between national brand and private label when the marginal effects and elasticities are evaluated based on actual observations rather than unobserved latent variables. Results show that private label FCOJ is considered as a normal (inferior) good if the income effect is assessed based on actual (potential) purchases. The estimated cents-off elasticities for private label FCOJ also vary substantially depending on which approach is used.

Key words: conditional expectation, elasticity, marginal effect, orange juice, selectivity bias, switching regression, unconditional expectation.

The modeling and empirical measurement of consumer preferences and behavior have been of great importance to demand analysts and marketing researchers. A common approach to these modeling efforts is to assume that various measures of individual behavior are determined in a utility maximization framework in which an individual selects one element from a discrete set of decision alternatives. Examples of such choice problems include decisions on travel mode, labor force participation, educational level, and brands of commodity purchased.

A frequently encountered problem in marketing research is the quantification of individual demand which may be influenced by unobserved behavior or preference; for example, a consumer may or may not purchase a particular product during the period of the survey. Also, individual-based data generally require researchers to deal with potentially biased estimates arising from the selection process that generated the sample. Recognizing this problem of individual self-selection, Heckman developed a procedure which transforms the problem from one of missing data on the dependent variable (no earning data for nonparticipants in the labor force) to one of specification error or

omitted variable resulting from sample selection bias. Following Heckman's study of labor supply, many econometric models have been developed to generate and estimate the conditional expectation of actions not taken. These models are generally called selectivity models.

Dolton and Makepeace examine the structure of a two-sector selectivity model with a probit selector equation. Assuming that selectivity bias is statistically significant, they investigate the appropriate interpretation of the sign of the sample selection coefficient. Dolton and Makepeace conclude that the notion of a correct sign for the selectivity coefficient is difficult to resolve on economic grounds and that any inferences from the results must be clearly qualified.

Many studies have extended the basic sample selection framework into a general class of econometric applications known as switching regression models. Empirical examples include demand for housing (Lee and Trost), brand name selection and orange juice consumption (Lee, Brown, and Schwartz), coupon promotional programs and demand for orange juice (Lee and Brown 1985), and at-home and away-from-home food expenditure patterns (Lee and Brown 1986). Switching regression models have provoked some interesting debate in econometric literature. Poirier and Raud argue that inherent confusion in the endogenous switching model specifications can cause ambiguous interpretation problems. However, as Maddala points out, the observational equivalence in model specifications

Chung L. Huang and Robert Raunikaar are professors and Sukant Misra is a postdoctoral associate, Department of Agricultural Economics, Georgia Experiment Station, University of Georgia.

The authors wish to thank Dale H. Carley, Joseph C. Purcell, and the *Journal* referees for helpful comments on earlier drafts of this manuscript.

which Poirier and Ruud observed essentially is two different ways of writing the same model (p. 285). He concludes that there is no ambiguity of inferences arising from endogenous switching models and that they are important and useful tools for many economic research applications. Nevertheless, the appropriate interpretation of coefficient estimates requires further exploration.

The primary objective of this study is to focus on proper analysis and interpretation of the empirical results from selectivity models. Similar to McDonald and Moffitt's analysis of the tobit model, this study explores the importance of economic interpretations of coefficient estimates. Specifically, the study will demonstrate how different approaches used for assessing marginal effects and elasticities from selectivity models may produce substantial differences in the interpretation of results. The following sections develop a generalized model for deriving conditional and unconditional marginal effects of the explanatory variables specified. An example from the literature is used to illustrate how qualitative interpretations may change when the marginal effects of the estimated model are evaluated with the proposed approach.

Selectivity Model Specification

The basic structure of a general selectivity model involving two regimes is considered. Given a sample of size T , let I_t^* be a $T \times 1$ column vector of an unobserved latent variable that separates the sample into two groups or regimes. Furthermore, it is assumed that $q_t^{(1)*}$ and $q_t^{(2)*}$ are $T \times 1$ column vectors that represent the quantity demanded for products 1 and 2 in regimes 1 and 2, respectively. Thus, the general model that consists of two regimes which describe consumer's demand for products 1 and 2 can be specified by a set of simultaneous equations such as

$$\begin{aligned} (1) \quad & I_t^* = S_{tk}\tau_k + \epsilon_t, \quad \text{for } t = 1, 2, \dots, T; \text{ and } k = 1, 2, \dots, K; \\ (2) \quad & q_t^{(1)*} = X_{tm}^{(1)}\alpha_m + u_t, \quad \text{iff } \epsilon_t > -S_{tk}\tau_k, \quad \text{for } m = 1, 2, \dots, M; \text{ and} \\ (3) \quad & q_t^{(2)*} = X_{tn}^{(2)}\beta_n + v_t, \quad \text{iff } \epsilon_t \geq S_{tk}\tau_k, \quad \text{for } n = 1, 2, \dots, N. \end{aligned}$$

S_{tk} , $X_{tm}^{(1)}$ and $X_{tn}^{(2)}$ are matrices of exogenous variables with T observations and the number of variables equals K , M , and N , respectively; τ_k , α_m , and β_n are parameter vectors with dimensions of $K \times 1$, $M \times 1$ and $N \times 1$, respectively. The residuals ϵ_t are normally distributed with

mean 0 and variance 1, and u_t and v_t are normally distributed with mean 0 and variances σ_u^2 and σ_v^2 , respectively. Note that $q_t^{(1)*}$ and $q_t^{(2)*}$ are observed conditional on I_t^* . Because the indicator I_t^* in the selection equation (1) is not observed, the partial samples of $q^{(1)}$ and $q^{(2)}$ are observed in terms of a binary variable, I , such that

$$\begin{aligned} (1.1) \quad & I = 1, \quad \text{iff } \epsilon > -S\tau_k, \\ & = 0, \quad \text{iff } \epsilon \geq S\tau_k. \end{aligned}$$

All subscripts, denoting observation t and/or variable k in the sample, have been omitted to simplify the presentation. The specification of equation (1.1) implies the familiar probit model

$$\text{Prob}(I = 1) = \Phi(S\tau_k), \text{ and}$$

$$\text{Prob}(I = 0) = 1 - \Phi(S\tau_k),$$

where $\Phi(\cdot)$ denotes the standard normal distribution function. Based on equation (1.1), the observed conditional demand equation in each regime can be rewritten as

$$(2.1) \quad q^{(1)} = X^{(1)}\alpha_m + u, \quad \text{iff } I = 1, \text{ and}$$

$$(3.1) \quad q^{(2)} = X^{(2)}\beta_n + v, \quad \text{iff } I = 0.$$

Given that in practice $q^{(1)}$ is observed if and only if $I = 1$, and $q^{(2)}$ is observed if and only if $I = 0$, there is a sample selectivity problem in the observed data. The problem arises because the model implies that the unobserved disturbance ϵ of the selection criterion equation is correlated with the unobserved disturbances of u and v of the demand equations (2.1) and (3.1). Following Maddala, the conditional expected demands for $q^{(1)}$ and $q^{(2)}$ are derived as

$$(2.2) \quad E(q^{(1)}|I = 1) = X^{(1)}\alpha_m - w^{(1)}\sigma_{u\epsilon}, \quad \text{and}$$

$$(3.2) \quad E(q^{(2)}|I = 0) = X^{(2)}\beta_n + w^{(2)}\sigma_{v\epsilon},$$

where $\sigma_{u\epsilon}$ and $\sigma_{v\epsilon}$ are the $\text{cov}(u, \epsilon)$ and $\text{cov}(v, \epsilon)$, respectively; $w^{(1)} = \phi(S\tau_k)/\Phi(S\tau_k)$, and $w^{(2)} = \phi(S\tau_k)/[1 - \Phi(S\tau_k)]$; and $\phi(\cdot)$ is the standard normal density function.

For estimation purposes, equations (2.2) and (3.2) are specified as

$$(2.3) \quad q^{(1)} = X^{(1)}\alpha_m - w^{(1)}\sigma_{ve} + \xi^{(1)}, \quad \text{and}$$

$$(3.3) \quad q^{(2)} = X^{(2)}\beta_n + w^{(2)}\sigma_{ve} + \xi^{(2)},$$

where $\xi^{(1)}$ and $\xi^{(2)}$ are new residuals with zero conditional means and heteroscedastic variances. In essence, the above specified model requires two steps in the estimation process. First, the probability of sample entry is estimated from equation (1.1) by a probit procedure; second, after estimates of τ_k , $w^{(1)}$ and $w^{(2)}$ are computed, they are added to equations (2.3) and (3.3) as omitted variables to account for sample selection bias. Given that the variance of the residuals is heteroscedastic in nature, equations (2.3) and (3.3) should be estimated by weighted least squares. In what follows, it can be shown that the conventional interpretation of marginal effects based on estimated coefficients is not strictly appropriate if demand equations include a subset of independent variables that also appear in the specification of the selection equation.

Conditional and Unconditional Marginal Effects

As Maddala points out, the marginal effects from the model can be assessed in three different ways, depending on the purpose of the research and the desired information (pp. 159–60). The first measurement of marginal effects can be derived in terms of the latent variables such as $q_i^{(1)*}$ and $q_i^{(2)*}$, which represent desired or potential quantities. If the objective is to predict the mean of potential quantities demanded, then the estimated coefficients, α and β , obtained from equations (2) and (3) would represent the appropriate marginal effects. In addition, two other measurements of marginal effects, conditional and unconditional, can be derived from the estimated model based on observed or actual quantities demanded. The following analysis focuses on obtaining predictions from the estimated model based on observed rather than unobserved potential quantities.

For simplicity, let z be the exogenous variable such that $z \in (S \cap X^{(1)} \cap X^{(2)})$. In other words, z represents a common explanatory variable which is included in the specification of equations (1.1), (2.3), and (3.3). By taking partial derivatives of equations (2.2) and (3.2) with respect to z , one obtains the conditional marginal effects of z on $q^{(1)}$ and $q^{(2)}$ as

$$(4) \quad \partial E(q^{(1)}|I=1)/\partial z = \alpha - \sigma_{ue}(\partial w^{(1)}/\partial z),$$

$$= \alpha + \tau\sigma_{ue}[(S\tau_k)w^{(1)} + (w^{(1)})^2], \quad \text{and}$$

$$(5) \quad \partial E(q^{(2)}|I=0)/\partial z$$

$$= \beta - \tau\sigma_{ue}[(S\tau_k)w^{(2)} - (w^{(2)})^2],$$

where α , β , and τ are parameters associated with the z variable in the demand and selection equations (Poirier and Ruud). As shown in equations (4) and (5), α and β alone account for only a portion of the marginal effects derived from equations (2.3) and (3.3). Thus, any interpretation of marginal effects based primarily on the α s and β s may be misleading because the effects of the second terms in equations (4) and (5) were not evaluated (Dolton and Makepeace). As noted earlier, equations (4) and (5) represent the marginal effects that are conditional on partial sample observations specific to each regime. Additional information can be derived based on all observations with respect to each product. Specifically, the unconditional expected values, $E(q^{(1)})$ and $E(q^{(2)})$, can be written as the probability of a regime being selected multiplied by the conditional expected value associated with the selected regime. Thus,

$$(6) \quad E(q^{(1)}) = \Phi(S\tau_k)E(q^{(1)}|I=1), \quad \text{and}$$

$$(7) \quad E(q^{(2)}) = [1 - \Phi(S\tau_k)]E(q^{(2)}|I=0).$$

Following McDonald and Moffitt, it can be seen that the marginal effects based on the total sample for a product can be decomposed into two parts:

$$(6.1) \quad \begin{aligned} \partial E(q^{(1)})/\partial z &= \Phi(S\tau_k)[\partial E(q^{(1)}|I=1)/\partial z] \\ &\quad + E(q^{(1)}|I=1)[\partial \Phi(S\tau_k)/\partial z], \\ &= \alpha\Phi(.) + \tau\phi(.)[X^{(1)}\alpha_m + (S\tau_k)\sigma_{ue}]. \end{aligned}$$

The first part represents the change in the observed $q^{(1)}$ weighted by the probability that regime 1 is selected; the second part represents the marginal probability, $\tau\phi(.)$, or the change in the probability of regime 1 being selected weighted by the expected value of $q^{(1)}$ if regime 1 is selected. Similarly, the marginal effects based on the total sample for product 2 in regime 2 can be shown as

$$(7.1) \quad \begin{aligned} \partial E(q^{(2)})/\partial z &= \beta[1 - \Phi(.)] \\ &\quad - \tau\phi(.)[X^{(2)}\beta_n + (S\tau_k)\sigma_{ve}]. \end{aligned}$$

In addition, the total unconditional marginal effect can be obtained from equations (6.1) and (7.1). Let q be the total demand for both $q^{(1)}$ and

$q^{(2)}$ regardless of whether it is observed for regime 1 or 2. By combining both equations (6.1) and (7.1), the effect of a change in the z variable on total demand for both products can be written as

$$(8) \quad \partial E(q)/\partial z = \alpha\Phi(.) + \beta[1 - \Phi(.)] \\ + \tau\phi(.)[(X^{(1)}\alpha_m - X^{(2)}\beta_n) \\ + (S\tau_k)(\sigma_{ue} - \sigma_{ve})].$$

The derivations of equations (6.1), (7.1), and (8) provide important economic interpretations for decomposing the unconditional marginal effects. In general, the interpretations of these equations are analogous to those offered by Thraen, Hammond, and Buxton for tobit analysis. Equation (8), for example, provides the basis for evaluating the unconditional marginal effect of an independent variable on the total demand for two products when the variable is included in the specifications of selection equation and the demand equations. The first two terms represent the quantity response due to actual purchase of the product and the last term is an adjustment factor for selectivity bias resulting from entry or exit from the market.

Depending on model specifications, slightly different formulas can be derived to evaluate unconditional marginal effects from estimated results. Necessary adjustments for assessing marginal effects under various model specifications are summarized in table 1. Equations (8)–(13) in table 1 are a guide for appropriate evaluation of the total unconditional marginal effect for any given independent variable on demand for $q^{(1)}$ and $q^{(2)}$. As shown in table 1, the need to adjust the estimated coefficients in the computation of unconditional marginal effects arises

only when an independent variable in the demand equations is included in the sample selection equation. The magnitude of the adjustment factors is the same regardless of whether the variable is included in both or only one of the demand equations. Therefore, the underlying factor determining whether an adjustment is necessary depends on the specification of the demand equation relative to the selection equation.

Empirical applications employing Heckman's procedure or tobit analysis are special cases of the general selectivity model in table 1. Specifically, equation (10) is applicable to a single regime model in which only a selection criterion and a demand equation are specified and Heckman's sample selection procedure is used in the estimation process (e.g., Cheng and Capps). In this case, the conditional marginal effects should be adjusted using equation (5). The unconditional effects can be evaluated and decomposed as shown in equation (10), except for the terms $X^{(1)}\alpha_m$ and σ_{ue} . Similarly, the tobit analysis is a special case of equation (12) in which the sample selection process is embedded in the demand equation as a single equation model. Thus, equation (12) corresponds to the unconditional marginal effect of $\alpha\Phi(.)$ for an explanatory variable, as McDonald and Moffitt demonstrated for tobit analysis.

Application and Interpretation of Results

The data used for the illustration in this study are drawn from a recent study by Lee, Brown, and Schwartz (LBS). They developed a switching regression model similar to that of equations

Table 1. Decomposition of Total Unconditional Marginal Effects for Various Selectivity Model Specifications

Equation	Variable z included			Marginal Effect of a Change in Variable z on Demand	
	(1.1)	(2.3)	(3.3)	Resulting from Actual Purchase	Selectivity Bias Adjustment from Entry or Exit from the Market
				$\alpha\Phi(.) +$

(1.1), (2.3), and (3.3) to examine the demand for national brand and private label frozen concentrated orange juice (FCOJ) in the United States. They used a two-stage estimation procedure for studying the joint determination of the self-selection process of brand labels and the demand for FCOJ. LBS reported that the demand for national brand frozen concentrated orange juice is more price responsive than that for the private label. They also found that socioeconomic and demographic characteristics generally have opposite impacts on the demand for these two products. Furthermore, LBS concluded that while national brand FCOJ is a normal good, the private label FCOJ is an inferior good and the consumption patterns are quite different between the two brands of FCOJ.

As previously discussed, marginal effects obtained from switching regression models may be assessed in terms of unobserved potential or observed actual quantities. LBS interpret their results on the basis of desired or potential effects. Thus, their interpretations of the results based on the estimated regression coefficients may be appropriate because the study's purposes and interests were focused on the latent variables of the model. However, for our study, the alternative interpretations based on observed quantities demanded are discussed using the LBS study. The analysis extends the LBS results to illustrate that additional information and different interpretations can be derived from the estimated results if the marginal effects are evaluated in terms of actual observations instead of unobserved latent variables.

Results of the LBS study are partially reproduced in table 2. The conditional and unconditional marginal effects were computed using equations (4), (5), and (8) based on the sample information and estimated parameters reported by LBS. Depending on the magnitude of the adjustment, the sign on marginal effect may differ from the estimated coefficient. For example, after selection bias was considered, the results suggest that female employment, female education, and female age all have negative rather than positive effects on per capita demand for private brand FCOJ (table 2). In general, the signs on marginal effects for national brand FCOJ were not changed, but the coefficients tend to be smaller relative to the LBS unadjusted estimates. For private label FCOJ, the signs on marginal effects in most cases were changed and these signs along with the size of the marginal effects become more consistent with those of national brand FCOJ.

From the perspective of commodity demand analysis, it is of interest to determine how various socioeconomic and demographic factors affect demand for FCOJ regardless of brand labels. To this end, the corresponding unconditional marginal effects are presented in table 2. Except for inherent conceptual differences, the interpretation of unconditional marginal effects is quite straightforward and does not require further elaboration.

As shown in table 2, this study suggests that a similar relationship exists between per capita demand for national brand FCOJ and private label FCOJ except for the presence of children and

^a Computed from equations (4), (5), and (8), respectively.

for households that reside in the southern region of the United States. Furthermore, if the income effect is based on actual rather than potential purchases, private label FCOJ is considered as a normal good rather than an inferior good, as LBS suggest. After adjusting for selectivity bias, the results show that the income effects based on actual purchases of national brand and private label FCOJ are .3327 and .3290, respectively. The consistency of the income effects suggests the demand for FCOJ reflects primarily differences in shopping behaviors with respect to brand name selection.

LBS reported that the elasticities for cents-off for national brand and private label FCOJ are .36 and .09, respectively. If, indeed, potential buyers of private label FCOJ are highly unresponsive to special cents-off price discount, an advertising campaign in the form of price discount is clearly not an effective method to promote the sale of private label FCOJ. However, if the marginal effects are based on actual purchases, the elasticities for cents-off are .33 for national brand FCOJ and .39 for private label FCOJ. Again, the analysis shows that consumers' response to special price discount in actual purchases are very similar for both national brand and private label, suggesting the effectiveness of special cents-off on FCOJ is about the same regardless of brand names.

Conclusions

The purposes of this study are twofold. First, the study calls attention to different approaches that may be used for analyzing the estimated selectivity model results. Second, the study demonstrates how qualitative interpretations may differ depending on whether the marginal analysis was based on potential or actual impacts. Furthermore, when an independent variable is included in the specification of a selection equation and the conditional demand equation, some adjustments may be required in order to appropriately assess the economic implications suggested by the data.

Using the demand for FCOJ as an example, the study suggests that the consumption patterns are quite similar between national brand and private label when the marginal effects are evaluated in terms of actual observations instead of unobserved latent variables. Specifically, the results show that private label FCOJ is considered

as a normal (inferior) good if the income effect is assessed based on actual (potential) purchases. The estimated cents-off price elasticities for private label FCOJ also vary substantially depending which approach is used in the analysis.

Although correction for self-selectivity bias is imperative for obtaining unbiased coefficient estimates, the study demonstrates the importance of distinguishing the different approaches upon which assessment of the empirical results and interpretations are based. The same approach can be applied to other forms of selectivity models, such as the popular Heckman sample selection procedure.

Erratum

Corrected materials are presented below for errors that occurred in an article entitled "The Demand for Canadian Fats and Oils: A Case Study of Advertising Effectiveness," by Ellen W. Goddard and Alex K. Amuah, in the August 1989 issue of this *Journal*, pages 741-49 (*Amer. J. Agr. Econ.* 71(1989):741-49).

Advertising Elasticities

The advertising elasticity table (p. 747) is erroneous. The corrected advertising elasticities are as follows:

Table 6. Advertising Elasticities

	Butter	Margarine	Shortening	Vegetable Oils
Mean				
Butter	.005	-.06	-.02	.003
Margarine	-.01	.04	.01	-.05
Shortening	-.04	.14	.03	.07
Vegetable oils	.04	.06	.02	.07
1986:4				
Butter	.001	-.05	-.02	-.02
Margarine	.0002	.05	.02	.01
Shortening	-.01	.08	.03	.05
Vegetables oils	.02	-.01	-.01	.0001

The text of the paper beginning with the first new paragraph, column 2, page 747 should be corrected as follows:

Regarding the cross-advertising effects, margarine advertising has had a negative effect on butter demand. On average, a 1% increase in the advertising of margarine leads to a 0.06% reduction in the demand for butter. The effect of butter cross-advertising on margarine is smaller than the cross-effect from margarine on butter on average. A 1% increase in the advertising of butter leads to a 0.01% decrease in the demand for margarine on average.

Vegetable oil advertising has a slight positive effect on butter demand. On average a 1% increase in the advertising expenditures of shortening leads to a 0.02% decrease in the demand for butter.

On average, margarine demand responds positively to shortening advertising. A 1% increase in the advertising of shortening leads to a 0.01% increase in the demand for margarine. Margarine responds negatively to vegetable oil advertising. A 1% increase in the advertising of vegetable oil leads to a 0.05% reduction in the demand for margarine.

Butter advertising has a negative effect on shortening and margarine demand. A 1% increase in the advertising of butter leads to a .04% decrease in the demand for shortening on average. Margarine advertising does not have a negative effect on shortening demand. A 1% increase in margarine advertising leads to a .14% increase in the demand for shortening on average.

A 1% increase in the advertising of butter leads to a .04% increase in vegetable oil demand. A 1% increase in the advertising of margarine leads to a .06% increase in vegetable oil demand. A 1% increase in the advertising of shortening leads to a 0.02% increase in the demand for vegetable oil.

The Impact of Increased LDC Food Production on LDC Food Imports: Comment

Patrick J. Gormely

If a less developed country (LDC) increases its food production, will its food imports decrease or increase? This question is of obvious importance not only to those concerned with development of LDCs but also to agricultural exporters in the United States and elsewhere.¹

In a series of papers (beginning with one in this *Journal*) de Janvry and Sadoulet (hereafter JS) have used simulation models to examine the impact of increased LDC food production on LDC food imports (1986, 1988; De Janvry, Sadoulet, and White). I offer a critique of their model after presenting a brief background to the debate.

Two Answers to the Question

Two opposing views exist. On one side are those who argue that increased food production will lead to decreased food imports. Examples are provided by the LDC "food gap" ("food crisis") literature that projects LDC food production, food consumption, and food imports. All the projections of which I am aware show that the more rapid the growth of food production, the slower the growth of food imports. In these projection models, the stimulus imparted to LDC economic development by a given increase in LDC food production is not large enough to cause an equivalent increase in food consumption, so food imports decrease.² Similar views have been expressed

by food exporters in the United States, who are worried that increases in LDC food production (perhaps caused by U.S. assistance to LDC agriculture) will lead to reduced LDC food imports. These groups, too, have in mind models of development wherein increases in LDC food production do not lead to equivalent increases in food consumption, so food imports decrease.

In striking contrast to these views, some economists have argued that increases in LDC food production will lead to increased LDC food imports.³ Mellor has long argued that exporters of food to LDCs will benefit from increases in LDC food production: "Perhaps surprisingly, policies which stimulate development of the domestic agricultural sectors of these countries are likely to provide the most rapid growth in their agricultural imports" (1978, p. 38). And, more recently, Mellor has argued that "It is one of the paradoxes of Third World Development that, as the rate of technological change in food production increases, many developing countries find demand increasing even more rapidly, with consequent increases in food imports. Bachman and Paulino (1979) show that rapid rates of Third World agricultural growth are associated with increases in food imports" (1988b, pp. 424-25).

Others who have recently argued that increased LDC food production will lead to increased LDC food imports include Houck, Kellogg, Paarlberg, and Purcell. These authors have in mind models of development wherein the stimulus imparted to LDC economic development by a given increase in LDC food production is large enough to cause more than an equivalent increase in LDC food consumption, so food imports increase.⁴

Patrick J. Gormely is an associate professor, Department of Economics, Kansas State University.

¹ Sometimes the issue posed is the impact of U.S. assistance to LDC agriculture on LDC agricultural imports from the U.S. This formulation introduces two additional, separate issues: the impact of U.S. assistance on LDC agricultural development and the U.S. share of LDC agricultural imports. These two separate issues are omitted here in order to focus on the central issue: the impact of increased LDC agricultural production (however caused) on LDC agricultural imports (from whatever source).

² FAO (1981) projects LDC food production and consumption to the year 2000, assuming both an "ambitious improvement" over past trends (scenario A) and a "modest improvement" over trends (scenario B). For 90 developing countries together, in the year 2000, scenario A's cereal production exceeds B's by 90 million metric tons (MT), but cereal consumption is higher by only 49 million MT, so cereal imports are 41 million MT lower.

Paulino also projects the food gap for year 2000. He says that "the potential food gap can ultimately be closed by accelerating [food] output growth in developing countries . . ." (p. 56). Also see IBRD (pp. 73-74).

³ Those so arguing share the hope that there is a harmony between the economic interests of U.S. and LDC agricultural producers.

⁴ I think these arguments are erroneous, but this is not the place for a detailed criticism. One point here will suffice. Mellor cites (as do many others) the Bachman-Paulino finding that the sixteen countries experiencing (during 1963-75) rapid growth of food production (58%) increased their food imports by 133%. Overlooked or ignored by all these authors is that Bachman-Paulino also showed (table 23, p. 86) that the 70 countries experiencing slower growth of food production (30%) increased their food imports by 332%. The Bachman-Paulino figures cannot serve as evidence that faster food production growth leads to faster food import growth. Specifically, Mellor's assertion of an association between rapid rates of agricultural growth and increased food imports is misleading.

The de Janvry-Sadoulet Simulation Model and the Interpretation of Its Results

The JS simulation model represents an important improvement in the tools brought to bear on the question of the impact of increased LDC agricultural production on LDC agricultural imports. As I hope is clear, my criticism is directed not against their important modeling effort but rather against their interpretation of its results.

In the JS model the LDC has three sectors: tradable agriculture (using labor and a fixed amount of land as inputs), nontradables (using labor and capital as inputs), and tradable industry (using labor and imperfectly substitutable domestic and imported capital goods as inputs).⁵ The assumption that tradable industrial production uses imported capital goods plays a key role. This assumption makes the quantity of foreign exchange available for importing capital goods a crucial constraint on economic growth. And this in turn means that agricultural growth's essential contribution to the LDC's total economic growth is to allow a reduction of agricultural imports, thereby freeing foreign exchange to pay for additional imported capital goods. How does a model making a reduction of agricultural imports a driving force in development end up predicting an increase in those same agricultural imports? It turns out that one or the other of two questionable assumptions is necessary.

The base-line simulation assumes that the LDC is exporting tradable industrial goods and importing both agricultural goods and capital goods. The model then simulates the impact of a limited technological change in agriculture on the volume of LDC agricultural imports. A 15% increase in land productivity is assumed. The technological change causes agricultural production to increase. The increase in agricultural production exceeds the consequent increase in agricultural consumption, so agricultural imports decrease. (Note that such an import decrease is predicted by both partial and general equilibrium static analysis.) The dynamic JS model now goes to work. The decrease in agricultural imports frees foreign exchange, allowing an increase in the importation of capital goods, thereby causing a subsequent increase in industrial production. After some years the cumulative growth of the economy and the consequent income increases are large enough to cause the increase in agricultural consumption to equal the original limited increase in agricultural production, thereby returning agricultural imports to their original level.⁶ This appears to support the JS conclusion that "tech-

nological change in LDC agriculture can create strong economy-wide growth and income effects with the potential of increasing the level of agricultural imports in future years" (1988 p. 1).

But this conclusion that the LDC's agricultural imports eventually return to and then go on to exceed their original level depends upon the unrealistic assumption of a limited increase in agricultural productivity. The assumption is unrealistic because, if development is constrained by the quantity of imported capital goods, it will presumably be in the LDC's interest to produce substitutes for all imports except the imported capital goods which it cannot produce. This means that the LDC will have an incentive to reduce agricultural imports as much as possible, so one cannot view the agricultural productivity increase as a one-time increase that will eventually be overcome by demand increases. A more realistic simulation is one incorporating a sustained increase in agricultural productivity.

In fact, JS report the result of a sustained increase of 1.4% per year in land productivity, but they give it inadequate attention. JS report that "with a sustained 1.4% productivity growth in agriculture and 0[%] productivity growth in industry, *import demand for food and feed grains falls continuously*, and the country eventually reaches self-sufficiency (1988, p. 21 and fig. 4). [My emphasis added.]

I suggest this simulation result destroys any claim of compatibility between increases in LDC agricultural production and increases in LDC agricultural imports. On the contrary, the JS model shows that sustained productivity growth in agriculture by itself will cause agricultural imports to decrease until they eventually reach zero.⁷

JS (1983) do show that if, in addition to the sustained productivity growth in agriculture, there is a large enough autonomous productivity growth in the industrial tradables sector, the demand for agricultural products will increase enough eventually to cause agricultural imports to return to and then exceed their original level. In effect, JS have shown that sustained agricultural productivity growth is compatible with agricultural import growth only if it is accompanied by sufficiently rapid autonomous growth of the industrial tradables sector. This is analogous to showing that the application of kerosene is compatible with extinguishing a fire if accompanied by the application of sufficiently large amounts of water! The word "compatible" is inappropriate in both arguments.

An Alternative Interpretation

At first glance it appears that the JS model supports the argument that increased LDC food production leads to increased LDC food imports. But the interpreta-

⁵ JS (1986) used a two-sector model. I focus on the latest formulation (1988).

⁶ JS (1988) reports two types of limited (15%) increase in land productivity. In the first the increase takes place all in one year; it takes more than 12 years for agricultural imports to return to their original level. In the second the increase in productivity takes place over 10 years (averaging 1.4% per year); it takes more than 17 years for agricultural imports to return to their original level.

⁷ Of course, productivity increases in agriculture can take the LDC beyond agricultural self-sufficiency, turning the LDC into an exporter of agricultural products.

tion of the JS results presented here shows this impression is wrong. The JS simulation shows an essential incompatibility between sustained LDC agricultural growth and LDC agricultural import growth, an incompatibility which can be prevented from manifesting itself only if there is sufficiently rapid autonomous growth in the nonagricultural parts of the economy. Contrary to first impression, the JS model supports the argument that increased LDC food production leads to decreased LDC food imports.

There has been in recent years a gradual change of emphasis in the argument of writers who see harmony between LDC agricultural growth and increases in LDC agricultural imports. In the past, some proponents of harmony argued or appeared to argue that LDC agricultural growth by itself could stimulate enough LDC economic growth to cause LDC agricultural imports to increase (Mellor 1978, 1983). Recent statements are sometimes more guarded, mentioning "growth arising autonomously in other sectors" (Mellor 1986), "some additional growth initiated outside of agriculture" (Mellor 1988a), and "growth independently generated in the rest of the economy" (Islam) as contributors to the economic growth that eventually causes LDC agricultural imports to increase. The JS model shows that these qualifications to the previous arguments are needed.

The Impact of Increased Food Production on Less Developed Country Food Imports: Reply

Alain de Janvry and Elisabeth Sadoulet

We are pleased that Patrick Gormely correctly restates, in his own language, the same conclusions which we have reached in our analyses of the impact of less developed country (LDC) productivity growth in cereals on their import demand for these same commodities: that, unless productivity growth in cereals is accompanied by productivity growth in other sectors of the economy or by additional income increasing measures, the LDCs cereal imports will decline. As Gormely also correctly points out, the significance of these results is to dismiss statements that have been made by many that conflicts between "aid" (the promotion of productivity growth in LDC cereals production) and "trade" (LDC cereal import demand) simply do not exist. We showed, through general equilibrium modeling, that there is a time path whereby import demand first tends to fall. Whether income effects, including those induced by productivity growth in cereals, eventually accelerate effective demand beyond domestic production depends on a number of structural features and policy interventions which allow the eventual achievement of harmony between aid and trade.

What remains unstated in Gormely's comment are two other fundamental aspects of these results. The first is that most LDCs cannot escape the need to increase productivity growth in their food/feed grains sector as a source of foreign exchange savings if their foreign exchange earning opportunities are not sufficiently buoyant in agroexports, mining, or manufacturing, an unfortunate reality for many late-coming LDCs in today's international economy. For this

reason, green revolution-type aid to LDCs is, perhaps unfortunately from the standpoint of more developed country (MDC) exporters, a necessary component of any meaningful aid program.

The second is that there exists a wide panoply of complementary developmental interventions that can be used to reduce this conflict, at least when calculating the present value of net trade effects with reasonable discount rates. These interventions include assistance to productivity growth in other sectors of the economy, particularly those which are more labor intensive and thus create larger multiplier effects on food demand. Reconciliation through productivity gains in manufacturing is consequently easiest in the newly industrialized countries where those other sectors are already large. Interventions also include the greater opening of MDC markets to LDC manufactures and agroexports as well as initiatives to reduce the debt burden on LDCs. Structural reforms that promote equity and policy reforms that reduce anti-labor biases also increase aggregate effective demand for cereals. Reforms that create income effects have the greatest long-run payoffs in terms of import demand in the lowest income countries since it is where budget shares and income elasticities for staple foods are the highest.

These results suggest that the reconciliation of eventual aid-trade conflicts requires going beyond a project-by-project approach to aid and relocating such interventions within the broader picture of their intersectoral, intertemporal, and interpersonal effects, a vision which has unfortunately been increasingly lost among international development agencies which have too often reduced the difficult task of development to the simpler one of project evaluation.

Marketing Order Impacts on Farm–Retail Price Spreads: Comment

Nicholas J. Powers

In a recent article in this *Journal*, Thompson and Lyon (TL) reported that the FOB–retail price spreads for California-Arizona (CA) navel oranges narrowed when marketing order handler prorates were suspended during the 1984/85 season (p. 657). TL's findings are suspect for several reasons.

One, TL's prices are for a heterogeneous commodity, which makes it impossible to accurately differentiate the effect of varying quality from a suspension. The composition of shipment grades and sizes changes over time (and even if they did not change, the proportion of shipments in each grade and size category does). This point is important because when shipments include relatively large volumes of undesirable sizes and grades, the price spread widens because of large shrink.¹

Two, TL's analysis is based on weekly data for the last half of the 1984/85 season and the subsequent two seasons. They did not identify the suspensions during the 1985/86 and 1986/87 seasons. Failure to correctly identify the suspension periods can influence the findings.

Three, TL's price spread specifications are suspect in lieu of the findings by Pick, Karrenbrock, and Carman that weekly price spreads for fresh CA navels display asymmetric response to changes in the FOB price and the lag adjustment to FOB price changes is one to three weeks.² TL also assumed that the marketing margin equations are in reduced form, but retail and FOB prices and shipments are determined simultaneously with handler's supply and the retail demand for navels. Consequently, an instrumental variable estimator is appropriate.

Four, TL's explanation of prorates' influence on price spreads is that producers and handlers favoring prorate maintained that the price spread increased as FOB prices fell while actual retail prices persisted at previous levels. Consumer advocates argued that the

availability of a greater quantity and a wider variety of sizes benefited consumers and narrowed price spreads (p. 649). This explanation is vague.

In this comment, the influence of a suspension on price spreads is analyzed by overcoming the last three problems of TL's article. The findings of this analysis illustrate that TL's findings are sensitive to the time period examined, data, and methods of analysis, and the comment also explains a suspensions' influence on price spreads. However, this analysis, like TL's, is limited by using average prices, which prevents an accurate measurement of the influence of varying product quality.

FOB-Retail Price Spreads

A static marketing margin equation similar to TL's is appropriate because such an equation is consistent with the monthly data of this analysis and the findings by Pick, Karrenbrock, and Carman that lag adjustments occur mostly within the month. The relative model is used to analyze the price spread (Wohlgenant and Mullen). In linear form it is

$$M_t = b_0 + b_1 RP_t + b_2 RP_t Q_t + b_3 MIP_t + b_4 APR_t + b_5 MAY_t + b_6 JUN_t + b_7 SUSP_t + e_t,$$

where the subscript t is the monthly observation, e is the residual term, the b 's denote the estimated intercept and estimated coefficients for the explanatory variables, M is the retail–FOB marketing margin for fresh navel oranges (the difference between the retail and the FOB prices), RP is the retail price, and MIP is the marketing input prices.³ While TL inserted a seasonal binary variable for May, in this analysis binary variables for the last three months of the marketing season (April, May, June) are included to measure seasonal effects. The influence of a suspension on average price spreads is measured by $SUSP$. The binary variable $SUSP$ equals one for a suspension and zero otherwise. In contrast with TL, this analysis identifies all of the suspension periods dur-

¹ In the produce industry, shrink refers to the difference between what is sold at retail and what is shipped by handlers. Most shrink is the result of product deterioration, with the product ending-up in the garbage bin.

² Two of TL's price spread series are the same as used by Pick, Karrenbrock, and Carman.

³ The marginal cost and markup models were eliminated as possible specifications for the marketing margin because the (unreported) results of the nested and nonnested tests clearly did not accept these models. Wohlgenant and Mullen reported similar findings for beef, but TL reported that the markup model was preferred to the others.

ing the 1982/83 to 1987/88 seasons.⁴ The monthly data are mostly from November through June for the seasons from 1979/80 to 1987/88.

Increases in the retail price and marketing input prices are expected to widen the marketing margin. Increases in the quantity of navel oranges are expected to widen the marketing margin if the supply curve of marketing inputs is upward sloping, which is plausible in the short run.

A larger proportion of fresh navels shipped during the later months of the marketing season is of lower grades, which results in greater shrink and larger price spreads for these oranges. The monthly binary variables account for the positive influence of these lower quality navels on the average price spread. CA Valencias is a substitute for navels which arrive on the market beginning in April. Its effect is indirectly measured by the influence on the retail price, which would fall when Valencias arrive and, thus, decrease the price spread. The negative influence of Valencias on retail prices is also partially imbedded in the monthly binary variables if their effect on retail prices is different from other demand shift variables.

Data and Estimation Procedures

Monthly U.S. retail prices are used in this analysis instead of weekly retail prices for the cities used by TL. City prices may reflect unique spatial factors. Because the data of this analysis cover a longer time period than TL's study, the data of this analysis display greater variation of market conditions. Such variation reduces the influence of conditions unique to one season on the findings. The monthly retail prices also allow for estimating the influence of a suspension for the United States rather than a few cities. Monthly data are adequate for this type of analysis, although prorate is administered weekly, because the NOAC revises its tentative weekly handler prorates about every month. Actual weekly prorates and tentative prorates are about equal.

⁴ Following the U.S. Department of Agriculture's development of program guidelines for administering marketing order regulations in early 1982, the department and the Navel Orange Administrative Committee (NOAC) for the first time suspended prorates before the end of the season. A suspension occurs when NOAC does not use prorate in the industry. The share of the annual crop shipped during the suspension varied from 12% to 53% during the 1982/83 to 1987/88 seasons. TL artificially distinguishes the 1984/85 suspension from the others by implicitly arguing that the 1984/85 suspension was entirely unexpected because it was announced only days before it went into effect. TL presumably thought that the effect of a "planned" suspension is different from an "unexpected" one. This distinction can be important conceptually, but, in practice, it is groundless for two reasons. First, USDA and industry officials had discussed plans to suspend prorate later in the 1984/85 season. Second, farm prices exceeded parity and were projected to do so for the remainder of the 1984/85 season, and the secretary of agriculture is instructed by the enabling federal marketing order legislation to suspend regulations under such circumstances.

Retail prices for fresh navels in cents per pound are from the Bureau of Labor Statistics (BLS), U.S. Department of Labor (USDOL). These average prices are collected throughout the month by surveying actual prices in supermarkets in eighty-five U.S. cities. These prices are weighted by the estimated stores' sales, which are weighted by navel sizes and grades. The marketing input price is an average of the producer price index for number two diesel fuel (1982-84 = 100), average hourly earnings index for non-supervisory workers in wholesale groceries and related products (1982-84 = 100), and average hourly earnings index for nonsupervisory workers in retail grocery stores (1982-84 = 100). These indexes are from USDOL. Weekly shipments of fresh CA navels to the domestic market (defined by the order as the continental U.S. and Canada) in million pounds are from NOAC's annual bulletin; they were used to construct monthly fresh-use shipments.⁵ Weekly shipments were lagged one week because three to seven days usually are needed to haul navels to retailers from handlers. Such lagging of shipments and FOB prices, which is consistent with Ward's analysis, accounts for transporting and handling navels. As a result the FOB prices for navel shipments more closely match with the retail prices for the same shipments. Monthly FOB prices for fresh CA navels in cents per pound are constructed by weighting the one-week lag of FOB prices by the one-week lag of fresh-use shipments. Weekly FOB prices are reported in weekly NOAC bulletins. These prices are collected from representative handlers and weighted by the handlers' fresh-use shipments, which are weighted by sizes and grades.⁶ Price data (*M*, *RP*, and *MIP*) are deflated by the consumer price index for all items (1982-84 = 1.00).

Because several suspensions began during the month rather than at the beginning or end of the month, a criterion was needed to identify these months as either a suspension or prorate month (SUSP).⁷ The three months that had between four to eleven days with the one-week lag of shipments from a suspension were identified as prorate months because the bulk of the one-week lag of shipments were from a prorate pe-

⁵ Data on shipments to Canada are unavailable, but industry personnel indicate that such shipments are a small share of domestic shipments.

⁶ For FOB price for fresh CA navels, and not the grower level price for navels, was used to compute the marketing margin (even though the enabling legislation for marketing orders is intended to affect farm prices), because the difference between the FOB and grower's prices, as reported by National Agricultural Statistics Service (NASS), USDA, is constant over the months of a marketing season. Consequently, the effect of a prorate suspension on marketing margins is the same, whether the FOB or grower's prices are used to compute the marketing margin.

⁷ Eleven of the 55 observations are from a suspension. TL had 42 observations for each city over a data period covering 77 weeks. TL consequently had about 8 or 9 observations during their 16-week suspension period, if the number of observations during the 1984/85 suspension is in proportion to the 42 observations over the data period covering 77 weeks.

riod. The one month that had seven days with the one-week lag of shipments from a prorate period was identified as a suspension.⁸

In contrast to the approach in TL's analysis, retail and FOB prices and shipments in the marketing margin equation are endogenous variables determined simultaneously with handlers' supply and the retail demand for navels.⁹ Predetermined variables appearing in the retail demand and supply as well as the marketing margin equations are normally used as instrumental variables when estimating the marketing margin equation (Johnston). The supply of fresh-use navels is heavily determined by the prorate volume (Thor and Jesse). When making the prorate decision, growers and handlers consider the price, volume ready for shipment, carryin, and other variables. The quantity of navels demanded at the retail level is affected by the price, income, and other variables. The per capita disposable income, carryin of navels, marketing input prices, and all binary variables consequently are the predetermined variables for this abbreviated model.¹⁰ These predetermined variables were used as the instrumental variables in the two-stage least squares (TSLS) estimation.

The small value of the Durbin-Watson (D-W) statistic in the preliminary analysis suggested a positive first-order autocorrelation scheme in the residuals. This autocorrelation may be partly caused by expanding exports. For models with first-order autoregressive errors, Fair indicates that the instrumental variables should include the predetermined variables in the system and also the one-period lag of all endogenous and predetermined variables. The marketing margin equation then are estimated by TSLS correcting for first-order autocorrelation in the residuals using the Cochrane-Orcutt procedure (Johnston).¹¹ The instrumental variables included the variables suggested by Fair.

Empirical Findings

The estimated results of the price spread model are

$$M_t = 1.436 + 0.461*RP_t + 0.035*RP_tQ_t \\ (0.272) \quad (9.463) \quad (2.611)$$

⁸ There were a few early months in several seasons when NOAC voluntarily did not use prorate because shipments are small and the crop had not matured, but these months did not pose any problem since retail prices were not available.

⁹ The prices for marketing inputs and services are assumed predetermined.

¹⁰ U.S. per capita disposable income in dollars is from the *Survey of Current Business*, U.S. Department of Commerce. It was deflated by the consumer price index for all items. Carryin was constructed by subtracting the actual total shipments prior to the beginning of the current month from the current season's estimated crop. Shipments and intraseasonal crop estimates are from the weekly and annual NOAC crop reports; they were lagged one week.

¹¹ The coefficients for the equations estimated by TSLS correcting for first-order autocorrelation are negligibly different from the coefficients estimated by OLS correcting for first-order autocorrelation. Thus, the findings are not sensitive to alternative estimation procedures.

$$+ 0.511*MIP_t + 0.381*APR_t \\ (0.108) \quad (1.070)$$

$$+ 2.522*MAY_t + 5.393*JUN_t \\ (3.570) \quad (5.045)$$

$$+ 0.972*SUSP_{t-1} \\ (2.108)$$

$$\text{Rho} = 0.798, R^2 = 0.892, \text{D-W} = 2.012. \\ (9.737)$$

The estimated coefficients have the expected signs and most are significantly different from zero based on asymptotic *t*-tests (in parentheses) at the 0.05 significance level. The estimated coefficient for the lagged residual term is denoted by rho, while the coefficient of determination is denoted by R^2 .

In contrast to TL, the estimated coefficient for *SUSP* indicates that the marketing margin increases by nearly 1¢ per pound during a suspension. If monthly estimates of the price elasticities of farm supply and retail demand were available, then the distribution of effects among handlers, retailers, and consumers could be approximated (Gardner). While estimates of such elasticities are not readily available, the magnitude of the margin increase is suggested by comparing this increase to several prices. For example, the 1¢ per pound increase in the marketing margin equals 3.7% of the average marketing margin, 2.3% of the average retail price, and 5.8% of the average FOB price.

In contrast to some of TL's findings, the marketing margin widens when the retail price increases but by much less than the increase in the retail price. Greater volumes also increase the marketing margin. The effect of greater volumes has two opposing effects on the marketing margin. The lower retail price (from greater volumes) reduces the marketing margin, but the greater volumes also elevate the price spread. The net effect on the marketing margin depends on the size of the resulting changes in the retail price and volumes. This analysis did not measure the effect of a suspension on volumes and prices and the resulting impact on price spreads, nor did TL.

Marketing input prices have a statistically insignificant effect on the marketing margin, as in TL's analysis, perhaps because of the relatively low variability displayed by this series.

In contrast to TL, the seasonal binary variables indicate that the price spread increases during the later months of the marketing season because a higher proportion of navels are lower quality, which elevates shrink, and perhaps the impact of competing Valencias.

Concluding Comments

In contrast to TL, this analysis indicates that the average price spread for navels widens during a prorate suspension. While the suspension effect could result

from a shift in market power between retail buyers and handlers, a more plausible explanation is that a greater proportion of the fresh navel shipments are of lower quality when prorate is suspended. The lower quality elevates shrink and, hence, increases marketing costs and the price spread. Since handler prorates tend to restrict shipments to the fresh use (Thor and Jesse, Shepard), handlers have a profit incentive to ship the highest quality navels to the fresh use when prorate is in effect because such navels bring the highest price and shrink the least. When prorates are suspended, profit incentives encourage handlers to ship all navels to fresh use which meet the minimum fresh-use quality requirements and will be sold at a price above the marginal variable marketing cost. Picking and shipping navels which enter processing is profitable for growers even though grower' returns are often negative because navels used in processing represent a part of the production base used in the marketing order from which the maximum quantity of navels eligible for the fresh use is calculated. For a grower, a larger production base means a greater maximum quantity of shipments to the higher-priced fresh use.

Marketing Order Impacts on Farm-Retail Price Spreads: Reply

Gary D. Thompson and Charles C. Lyon

In his comment, Powers presents four main criticisms of our article and attempts to remedy the flaws he perceives by estimating an alternative price spread model. In this reply, we shall first deal with Powers' criticisms and then comment on the adequacy of his revisions on our work and the credibility of his results.

Powers' first criticism is that because of inadequate data, we were unable to capture important quality differences in a "heterogenous" commodity. On the contrary, the weekly FOB price series used in our analysis were constructed by calculating an FOB price weighted by size, grade, and production district price differentials (Thompson and Lyon, p. 651). The three weighted market-level FOB series thus reflected changes in the volume of undesirable sizes and grades. Because FOB prices for only those sizes of oranges for which retail prices were collected were used to construct the FOB series, our weighted FOB prices conformed closely to the prices reported in our retail price series. Thus, the three price series explicitly captured quality effects. Any potential bias introduced by ignoring grade and size changes through time was thereby avoided. As acknowledged by Powers, this bias cannot be remedied with the aggregate data he employs. This is a crucial point because Powers concludes that deteriorating product quality at the end of the season should cause price spreads to increase.

Powers' second criticism suggests that we failed to properly identify weeks during the 1985/86 and 1986/87 marketing seasons when the industry also operated without prorate. Our analysis defined the period of prorate suspension as having occurred when the U.S. Department of Agriculture (USDA) unilaterally suspended prorate during the 1984/85 season. We considered the 1984/85 suspension to be fundamentally different from subsequent periods because of the unique circumstances leading up to the suspension. First, market conditions were markedly different. Freezes in 1984/85 in Florida and Texas left California-Arizona (CA) fresh navel oranges with almost no competing supplies during the 1985 marketing period. Second, a majority of the fresh domestic crop had not yet been shipped. When USDA announced the suspension (beginning the first week in February

of 1985 and extending for 18 consecutive weeks until the end of the season), only 37.6% of the crop had been shipped under prorate (Navel Orange Administrative Committee [NOAC] *Annual Report*, 1985). Third, and most important, the prorate suspension in February 1985 was virtually unanticipated. Industry officials admit that the secretary of agriculture's decision to suspend the prorate caught them off guard.¹

In contrast, removal of prorate during the 1985/86 and 1986/87 seasons was fully anticipated, was of shorter duration, and occurred under much different supply conditions. At the beginning of the 1985/86 season, USDA notified NOAC on 25 November 1985 that USDA would issue weekly volume regulations based upon criteria established by NOAC. After protracted discussions among committee members, NOAC finally agreed on 23 February 1986 to three criteria upon which to base the decision to suspend the weekly prorate.² The prorate in the 1985/86 season was suspended after the week ending on 13 April when two of the three criteria were met. This suspension was clearly anticipated and nearly two-thirds of the fresh domestic shipments had already been accounted for. Rules regarding suspension of the prorate were even more stringent during the 1986/87 season as NOAC proposed on 30 October 1986 that volume controls be imposed in each week through the week ending on 23 April 1987; these proposed regulations were accepted by USDA, and 79.9% of the season's fresh domestic crop was shipped before prorate was suspended. In both these seasons, supply conditions permitted larger shipments from Texas and Florida than during the 1984/85 season. Thus the "suspensions" occurring in the 1985/86 and 1986/87 were clearly different from the 1984/85 suspension in important ways. Acknowledging these dissimilarities, we isolated the 1984/85 suspension as the cynosure of our analysis, thereby permitting examination of industry and market reaction to this unanticipated supply-side policy shock.

¹ Industry officials indicated that the decision to suspend the prorate was not expected because it was one of the more severe options available to the secretary of agriculture and there appeared to be little precedent for such an action.

² NOAC agreed that prorate should be suspended when any two of the following criteria were met: (a) the remaining volume in the largest district—District 1 in central California—was less than 11,500 carloads (26% of the actual shipments from District 1 in 1985/86 or 24% of total shipments from all four districts); (b) weekly fresh domestic shipments of California-Arizona Valencia oranges exceeded 200 carloads; and (c) FOB prices had not declined in three consecutive weeks following the weeks ending on 27 Feb. 1986.

Powers' third criticism actually embodies two separate but perhaps related issues; dynamic price transmission and simultaneity. In either case, how our results are suspect in light of the Pick, Karrenbrock, and Carman (PKC) study is not made clear. The thrust of the PKC work appears to be in explaining price transmission, not how prorate affect marketing margins. Consequently, the models employed by PKC explain marketing margins only as a linear function of current and past prices; no variables—other than a time trend—purporting to explain margins are included in their specification. Furthermore, in the margin equation specified by PKC the dependent variable is not the FOB-retail margin but rather the change in the margin from one week to the next (Pick, Karrenbrock, and Carman, p. 77). Thus, while our analysis concentrates on explaining the magnitude of the spread between FOB and retail prices, the PKC analysis focuses on changes in this spread. This discrepancy leads us to question strongly the relevance of the PKC results either as a basis to refute our results or as support for the model proposed by Powers. Moreover, if simultaneity is a problem in price spread models as Powers suggests, then the PKC results must also be questioned. Even if the PKC results were directly applicable, however, the results of our diagnostic tests for first-order autocorrelation within and across equations provide indirect evidence that the omission of lagged values of retail prices did not lead to misspecification.

The issue of simultaneity was addressed in our article (Thompson and Lyon, p. 649). We explicitly noted that use of weekly price data precluded specification of a structural model. While aggregation of weekly data into monthly observations would have permitted such a specification, this was undesirable for both practical and theoretical reasons. Practically, aggregation would have resulted in the loss of sufficient data points during the prorate suspension on which to base the analysis. Indeed, the unique nature of the dataset would have been forfeited, rendering a valid "with and without" comparison of industry behavior under marketing order quantity controls infeasible. Because this was the prime advantage of the weekly data, the disaggregated nature of the dataset was retained and the reduced-form equations specified. This enabled us to identify fifteen data points during the 1984/85 suspension period. Monthly data would have reduced the number of data points to four. Furthermore, use of monthly data requires specification of a monthly dummy variable (such as that employed by Powers) tracking suspensions which occur at any week during a given month. This necessarily provides an imprecise measure of the impact of suspensions because both suspension and nonsuspension weekly observations are aggregated into monthly observations.

More important from a theoretical perspective, monthly observations are inconsistent with the institutional setting of the industry. This is because the CA naval orange prorate is a weekly policy instru-

ment used to regulate market flows. Powers' claim that prorates are set largely on a monthly basis is not consistent with the fact that actual prorate allotments are announced only three to ten days prior to the period of regulation (USDA 1988). In addition, announced prorate quantities are commonly revised by NOAC once, twice, and even three times before the end of the weekly period of regulation (NOAC Weekly Bulletins). Clearly then, producers, handlers, and distributors cannot consider tentative prorates to be equivalent to actual prorates. Indeed, if one assumes that weekly prorates and tentative prorates are "about equal," then the unanticipated events of the 1984/85 seasons are not subject to analysis.

To remedy the simultaneity, Powers argues that an instrumental variable estimator is necessary. Because nearly all the price spread models referred to in the literature have been reduced-form models (e.g., Wohlgenant and Mullen), the question of appropriate estimators is seldom addressed. The justification for utilizing an instrumental variable estimator lies in the possible correlation between the explanatory variable and the error term, whether the cause of the correlation derives from simultaneity or other sources. Recent small sample results suggest that instrumental variable estimates may provide little improvement over OLS estimates (Nelson and Startz). In any case, simultaneity would appear to be less of a problem in a short-run model based on weekly observations than in a longer-run model utilizing monthly data. We suspect that retail demand schedules for navel oranges did not shift about radically from week to week. On the supply side, seasonal supply schedules are predetermined for biological reasons, although intra-seasonal supply schedules might conceivably shift. Regardless, these hypotheses can be checked indirectly by comparing the vector of parameter estimates obtained from OLS and two-stage least squares using the Hausman test for errors in variables in single equation models (Hausman).³ We could think of applying an analogous test for the difference between the seemingly unrelated regression estimates and three-stage least squares estimates, but, for the same reasons we could not specify a structural model, we have no appropriate set of instruments with weekly observations for three-stage estimation.

Parenthetically, it should be mentioned that contrary to Powers' assertion, neither the retail price data nor the FOB price data used by PKC were the same as the data used in our analysis. We augmented our retail price series with independently gathered advertised prices. In addition, we employed a different FOB price series than did PKC and Powers. Powers and PKC used an FOB price series reported by NOAC. As noted in our article, we used the FOB prices re-

³ Powers comments that the OLS and two-stage least squares (TSLS) estimates for his model are negligibly different. This result gives circumstantial evidence that the purported impact of simultaneity is itself negligible or that the instruments used in the TSLS estimation did little to purge the endogeneity.

ported in the Western Citrus Report (WCR), which publishes weekly sales prices for every size and grade of navel orange sold by production district. As mentioned above, these data enabled us to adjust for quality differences. Further motivation for the use of the WCR data in lieu of the NOAC data is found in an ERS study (USDA 1985) which notes that the weekly NOAC FOB series represents prices quoted by handlers rather than actual sales prices. This same study states that the NOAC quoted prices are generally viewed within the industry as inaccurate reflections of actual selling prices.

Powers' final criticism that our "explanation" of the influence of prorate suspension on price spreads is "vague" appears to be misplaced. We referred to the difference in opinions between some producers and consumer advocates in the introductory description of the CA navel orange industry because this lack of consensus provided one justification for studying margin behavior under prorate suspension. These conflicting views of price spread behavior were never offered as an explanation in subsequent sections of the article.

Turning now to the alternative specification presented by Powers, the estimation results appear suspect for a number of reasons. The monthly data employed are not only theoretically inconsistent but are, by their very nature, inadequate to capture changes in FOB-retail price spreads. While weekly FOB prices are relatively stable, in-store retail prices fluctuate

significantly from week to week. In addition, supermarkets advertise sale prices periodically for navel oranges as loss leaders. Monthly average retail prices from the Bureau of Labor Statistics do not adequately reflect important weekly changes in navel orange prices. Aggregation across eighty-five cities suggests as well that potentially important spatial differences cannot be accounted for. Failure to capture the true extent of price variability, particularly that variability resulting from quality changes, may be one reason for the increasing margins at season's end indicated in Powers' estimation results.

Reestimation of the Markup Model

Of Powers' four criticisms, the "failure" to properly identify suspension periods is potentially the most damaging. We have already indicated why the 1984/85 suspension was unique. We were curious, nonetheless, to explore how our estimates might have changed had we included all other "suspensions," as Powers exhorts. Accordingly, we reestimated two variations on our original markup model. In the first, we included a dichotomous variable, *DSUSP*, set equal to one for any week in which prorate was not in effect during all three seasons. In the second, we decomposed the effects of removing the prorate by including two dummy variables, one for weeks during the 1984/85 suspension (*D1984/85*) and a second

<i>MDL</i>	0.02 (0.28)	0.64 (5.31)	-5.00E-5 (-0.48)	0.00064 (0.06)	0.0013 (0.16)		-0.03 (-2.69)	0.0003 (1.86)
<i>MSF</i>	-0.20 (-1.65)	1.01 (11.47)	8.00E-4 (1.13)	-0.014 (-1.90)	0.0099 (1.78)		-0.03 (-4.01)	0.0002 (0.16)

^a *DOTHER* equals one when prorate is suspended in the 1985/86 and 1986/87 seasons; otherwise *DOTHER* equals zero.

^b *t*-statistics are in parentheses.

for non-prorated weeks occurring in the 1985/86 and 1986/87 seasons (*DOTHER*). All remaining data and variables are identical to those referred to in our article.

Had we mistakenly lumped all prorate "suspensions" into the same dichotomous variable (*DSUSP*), the effects of removing prorate would have appeared to be insignificant for all three cities (see table 1). The magnitude of the estimates and their large standard errors do not provide much basis for inferring the validity of Powers' results or ours. In fact, had we initially obtained these results, we would likely not have attempted to publish them. Alternatively, when two separate dummies for non-prorated periods in the 1984/85 (*D1984/85*) and 1985/86–1986/98 (*DOTHER*) seasons are specified, decreases in the price spreads for Atlanta and San Francisco in the 1984/85 season are strikingly similar to those reported in our article. These results indicate that the effect of the 1984/85 prorate suspension was clearly different from non-prorated periods in subsequent seasons. These empirical results are consistent with the fact that the circumstances surrounding the 1984/85 prorate suspension were substantially different from other prorate "suspensions."

We might speculate that with data from additional seasons included in the empirical analysis, the positive impact on price spreads of additional "suspensions" which occur at the end of each season would ultimately swamp the negative impact of the 1984/85 suspension if all suspension periods are included in single dummy variable. The estimation results of Powers' price spread model tend to substantiate this speculation. Yet, in light of the unique nature of the 1984/85 suspension, we continue to conclude that FOB–retail price spreads in two geographically disparate cities declined significantly when the prorate was suspended in 1985.

Finally, we would like to take this opportunity to correct a typographical error in the original article. In table 2, the first independent variable in the relative model should be price.

Rice in Asia: Is It Becoming an Inferior Good?

Comment

Jikun Huang, Cristina C. David, and Bart Duff

In a recent article in this *Journal*, Ito, Peterson, and Grant (IPG) investigated the nature of demand for rice in fourteen Asian countries using a generalized covariance demand model. This model was estimated from pooled time-series-cross-section data from 1961 to 1985 for three groups of countries classified by changes in per capita rice consumption levels. Rice consumption per capita was specified as a function of per capita gross domestic product (GDP) in real terms and the ratio of world price of rice to wheat. Because income elasticities tend to be lower at higher income levels, a log-inverse-log model was adopted and ridge regression was employed to minimize multicollinearity problems between $\ln Y$ and Y^{-1} . The results indicated that income elasticities have significantly declined. Moreover, income elasticities are negative in half of the countries studied, leading to the conclusion that rice is becoming an inferior good in Asia.

The fact that income elasticities for rice and other staple food decline as income increases has long been established (Alderman, Bouis 1989). However, for comparable years, IPG's estimates are much lower than country-specific estimates of income elasticities in Asia based on either cross-section or time-series data, which are nearly all positive (table 1). While the latter pertain mostly to estimates for the 1970s, negative income elasticities for low-income countries such as Nepal and Bangladesh seems implausible. Even for a rapidly developing country such as Thailand, income elasticities may be expected to become negative only sometime in the 1980s. Only for Japan, Taiwan, Singapore, and Malaysia, where per capita incomes are relatively high, can negative income elasticities be expected. This comment demonstrates that problems with definition of income and price variables as well as application of ridge regression have led to underestimation of income elasticities in the IPG study.

Problems of Estimation

Estimation problems include such specification issues as those related to income and price and the sometimes misleading results of ridge regression.

The authors are, respectively, a research fellow, and agricultural economists, the International Rice Research Institute, Manila, Philippines.

The authors are grateful to Yujiro Hayami, Keijiro Otsuka, and the *Journal* reviewers for their suggestions.

Specification Issues

Income. IPG defined income as per capita GDP in real terms measured in domestic currencies. With cross-country pooled data, this means that rice consumption was regressed on income measured in different currencies. In a generalized covariance model, OLS estimate of the parameters, $\beta = [X'X]^{-1}X'Y$, is invariant to differences in measurement units across countries. However, in ridge regression, β is estimated as $[X'X + kI]^{-1}X'Y$, where k is defined as the ridge factor. Addition of the constant value k to all elements in the $X'X$ matrix measured in different currencies will result in a different estimate of the parameters for the pooled cross-country data from separate regressions for each country. Differences in estimated income elasticities across countries therefore will reflect not only the effect of preference but also differences in the unit of measurement of income.

Another problem is use of per capita gross domestic product (GDP) rather than disposable income or private consumption expenditure which better reflect the budget constraint of consumers. GDP includes government expenditures which usually increases faster than other components of domestic product. Hence, use of GDP instead of more appropriate measures of consumers' income will result in underestimation of income elasticity.

Price. Consumer demand for a commodity depends on, among others, domestic prices. In most Asian countries, the government intervenes extensively in the rice market and, to a lesser extent, also in the wheat market. Thus, domestic prices of these commodities will diverge from world market prices in varying degrees across countries and over time. Indeed, variations in the price ratio of rice to wheat across countries as a result of differential rates of nominal protection between the two commodities ranged from 0.20 in Burma to 3.84 in South Korea in 1986. Conversely, the ratio of world prices increased by 31% from 1961 to 1985, whereas in twelve out of the fourteen countries, the ratio of domestic prices increased ranging from 3% in Nepal to 178% in South Korea in the same year. Only Singapore and Burma had declining ratios of domestic prices. IPG's use of world prices instead of domestic prices is inappropriate in such policy environment.

Ridge Regression

Brown and Beattie have shown that ridge estimation of some models can give poor or misleading results. Significantly biased coefficients will be estimated when the model includes: (a) positively correlated variables that have true coefficients with opposite signs and highly unequal magnitudes or (b) negatively correlated variables that have true coefficients with the same sign but large unequal magnitudes.

Although all variables may not be positively or negatively correlated in a generalized log-inverse-log model with country dummy variables, the bias can be very large due to the special nature of the model. Besides price and income, four other sets of variables are highly intercorrelated, i.e., $\{y^{-1}, \ln y\}$, $\{d_i y^{-1}, d_i\}$, $\{d_i \ln y, d_i\}$, and $\{d_i y^{-1}, d_i \ln y\}$, where d_i is the dummy variable for country i . In addition, the magnitudes of the coefficients for these correlated variables are very different when income elasticities (e) are assumed to change over time.¹ Use of ridge regression in the IPG study without incorporating a priori information may, therefore, have led to biased estimates.

A Reestimation

Because IPG's analysis is subject to a number of econometric problems and the extent to which measurement problems of income and prices affect the estimates of income elasticities can only be determined empirically, the model was reestimated with several changes. First, income is defined as per capita private consumption expenditure (PCE) in real terms (deflated by consumer price index) and expressed in U.S. dollars converted by the purchasing power parity (PPP) exchange rate for 1980.² Second, the ratio of domestic price of rice to wheat flour has been used. Third, Sri Lanka is excluded from the

analysis because of limitation of price data. Data for rice consumption, population, and income are from the same sources as IPG's except for the PCE for Bangladesh, which is from the Asian Development Bank. Domestic prices of rice and wheat are from individual country sources. The PPP's are from Pardey and Roseboom.

To minimize possible bias in use of ridge regression in the log-inverse-log demand model, the following additional a priori information were considered in choosing the optimal k -value: (a) k should be small;³ (b) the coefficient of Y^{-1} is expected to be negative;⁴ and (c) average level of estimated income elasticities (e) obtained from log-inverse-log model over the study period should not be very far from the constant elasticities (e^0) derived from the double-log demand model using OLS.⁵

The general procedure for choosing the optimal k -value are as follows. Based on k values ranging from 0 to 1, a set of k 's, say A , which generate relatively stable trace is identified. From this, a subset B , is selected such that the condition of negative coefficient of Y^{-1} is generally satisfied. Finally, the "optimal" k is chosen to be the lowest k which provide estimates that largely satisfy condition (c).

Results

The estimates of coefficients based on the revised measures of income and price as well as alternative choice of k values are presented in table 2, and the estimated income elasticities are reported in table 3. The new estimates of income elasticities are, in general, higher than the IPG results. Only Japan, Malaysia, Singapore, Taiwan, and Thailand have neg-

¹ Because $e = c - b/Y$, where c is the coefficient of $\ln Y$ and b of Y^{-1} , then b is expected to have a much large value than c . Suppose $e_{1961} = .3$, $e_{1987} = .1$, $Y_{1961} = 1000$ and $Y_{1987} = 2000$; then $b = -400$, $c = -.1$ and $b/c = 4000$.

² In China, national income is used due to lack of reliable data.

³ Because it is undesirable to introduce excessive bias, one should be conservative in increasing k , particularly in the case of the log-inverse-log dummy demand model as explained above.

⁴ This is based on the earlier observation that income elasticities decline as income increases.

⁵ While the double-log model does not allow for changing income elasticities, it provides estimates derived by unbiased OLS estimation which can serve as a reference for the average income elasticity.

¹ $k^* = .002$, $.01$, and $.0005$ for group 1, group 2, and group 3, respectively.

ative income elasticities among the thirteen countries analyzed.⁶ Income elasticities for Bangladesh and Nepal are now positive. For Nepal, elasticities have increased over time because per capita consumption expenditure in real terms apparently declined. Korea shows a slightly rising income elasticity which may be explained by the significant substitution of rice for barley in the diet during the study period which has not been taken into account in this simple model.⁷ Finally, among countries with positive income elasticities, these have declined more gradually than the IPG estimates.

Sensitivity Analysis

The estimated coefficients of income variables and thus, the derived income elasticities are sensitive to the choice of k -value (tables 4 and 5). Based on the ridge trace rule, optimal k -value might be 0.1 for all three country groups. However, at $k = 0.1$, some prior information is violated in many countries. The coefficients of Y^{-1} for all countries in group I are positive implying that income elasticities increase as incomes rise. Furthermore, average estimated income elasticities over the study period for Nepal and Thailand are far from those derived using double-log model. In group II and group III, most countries' e are far from e^0 . By incorporating three prior infor-

mation sets and following the estimation procedures outlined earlier, we chose $k = .002$ as optimal for group I. In group II, since only positive coefficients of Y^{-1} can be obtained for Bangladesh and Korea over any k ranging from zero to one, $k = .01$ which provides the relative small positive value coefficients and meet all other criteria is chosen. At $k = .0005$, all criteria are satisfied for group III countries.

Concluding Remarks

Our analysis indicates the IPG estimates of income elasticity are significantly understated.⁸ While income elasticities will undoubtedly decline as income increases, only Japan, Taiwan, Singapore, Malaysia, and Thailand have income levels that support negative estimates of income elasticities for rice. However, the population and rice consumption of these five countries account for less than 10% of the totals for Asia. In most Asian countries, therefore, rice is not an inferior good; and income elasticities for rice, given the relatively stable elasticity trend in table 3, will likely remain positive throughout the 1990s.

The implication drawn by IPG that "there is a potential for excess supplies of rice to develop in Asia, putting downward pressure on rice price" is not only

⁶ The negative income elasticities for Thailand in the 1960s and 1970s remain implausible. The underreporting of rice exports due to high export taxes during that time may have understated per capita rice consumption in the early period.

⁷ This substitution has run its course, and thus rice consumption per capita may be expected to decline in Korea in the future.

⁸ Bouis (1990), in another comment on the IPG's study, argued that growing urbanization and increasing commercialization of rice production, not simply increasing income per se can explain decreasing national per capita rice consumption. If these factors are properly taken into account, revised estimates of income elasticities are expected to be even higher. This is confirmed by our preliminary estimates of an Asian cereal grains demand model that includes urbanization effect.

based on faulty estimation but a very simplistic view of the rice situation. Future rice supply prospects are not expected to be strong (Levine et al., David). The land frontier in most Asian countries is essentially closed. Crop area planted to rice has not grown throughout the 1980s. The easy gains from the green revolution technology have been reaped and the possibility of further raising yield frontiers is uncertain. Low current world rice prices reduced incentives for public investments in irrigation and technological research throughout the 1980s. Yet, population growth rates in Asia are projected to increase at near 1.8% (United Nations). Even if the income elasticities for rice were low, it is not clear that the supply-demand outlook warrants the implications drawn by the authors.

Rice in Asia: Is It Becoming a Commercial Good? Comment

Howarth E. Bouis

Ito, Peterson, and Grant (IPG) have recently shown that rice income elasticities are highly negative in many Asian countries and only slightly positive and declining over time in other Asian countries. Their results, if accurate, have obvious and important implications for how Asian governments, international lending agencies, and the CGIAR system should allocate resources in anticipation of weak demand and continued low international prices for rice.

This comment argues that IPG fail to consider the effect on demand for rice of decisions by semisubsistence farmers to produce rice, which leads to downwardly biased time-series estimates of aggregate national income elasticities. That is, demand effects that IPG attribute to trend increases in aggregate per capita income may largely reflect instead (a) a concurrent rural to urban migration pattern, (b) the decreasing importance over time of aggregate rice production within some Asian countries, and (c) a declining share of semisubsistence production within the rice sectors themselves.

Income Elasticities Derived from Expenditure Surveys

A useful starting point for arguing that production and consumption decisions for staple foods cannot be analyzed separately for Asian countries is to note that rice income elasticities derived from expenditure surveys are nearly always positive and in some instances considerably above zero. For example, Timmer and Alderman estimate an aggregate national income elasticity for rice for Indonesia of about 0.4 from household expenditure survey data collected in 1976. Pitt derives an estimate for Bangladesh of about 1.0 for 1973–74, and Trairatvorakul derives an estimate for Thailand of 0.13 for 1975–76 (see Alderman, table 12, for estimates for other countries).¹ The corresponding IPG estimates are 0.19, –0.04, and –0.25 for Indonesia, Bangladesh, and Thailand, respectively, for the survey years cited above.

The same comparison shows a similar result for a developed economy. IPG derive an estimate of –0.71 for the income elasticity of demand for rice in Japan for 1984, where household income averaged about

\$40,000 per year for a family of four.² Intuitively, such a high negative elasticity implies that budgets are so constrained that Japanese households consume rice in large amounts out of rather dire necessity. If incomes double and households reduced rice consumption by 70%,³ what (calorie dense) foods would these households eat instead which they could not already afford? In table 1 rice expenditure data presented by expenditure group for Japan suggest that higher income groups do not drastically reduce rice consumption as incomes increase.

How does one reconcile declining per capita rice consumption over time with such food expenditure information? Table 2 summarizes rice consumption data, disaggregated by expenditure quartile from food expenditure surveys in six less developed Asian countries. Controlling for urban and rural populations, per capita consumption of rice increases monotonically with income, except for Thailand where the arc income elasticity is close to zero. Comparing rice consumption levels within the same expenditure quartile, rural consumers consume more rice than urban consumers. The most pronounced and consistent difference between urban and rural consumption across income groups occurs for Thailand. IPG estimate that the aggregate income elasticity for rice for Thailand had fallen to –0.44 by 1985.

Explanations for Rural-Urban Demand Patterns

Lower rice consumption in urban versus rural areas has several possible explanations. First is the explanation put forth by IPG (although not in this particular context) that urban incomes are higher and that higher income consumers prefer to substitute more preferred foods for rice. However, this explanation does not go very far in explaining the large differences across urban and rural populations within the same expenditure quartiles indicated in table 2, nor is it supported by the trend in rice consumption across income quartiles, controlling for urban/rural.

Second, assume that two persons with the same set of demand preferences and levels of income and fac-

² GNP per capita in 1984 was US \$10,580 at current prices (World Bank, p. 340–41).

³ IPG cannot appeal to lower income elasticities closer to zero at, say, a household income of \$80,000 because their estimates appear always to become increasingly negative at higher income levels.

Howarth E. Bouis is a research fellow at the International Food Policy Research Institute, Washington, D. C.

¹ The estimate cited for Pitt is for rural households only.

Data sources (see also Bouis 1989b for other details): Bangladesh: *Household Expenditure Survey of Bangladesh 1973-74*, Bangladesh Bureau of Statistics; data are disaggregated by household expenditure quartile instead of per capita expenditure quartile. India: *Second Quinquennial Survey on Consumer Expenditure*, undertaken by the Department of Statistics from July 1977 to June 1978. Indonesia: Data are taken from SUSENAS 1981 expenditure surveys, as reported in Rosegrant et al. (1987). Pakistan: *Household Income and Expenditure Survey 1984-85*, conducted by the Federal Bureau of Statistics. Sri Lanka: Data are taken from the *1980/81 Labour Force and Socio-Economic Survey* conducted by the Bureau of Census and Statistics, as cited in Sahn (1984). Thailand: Data taken from the *1975/76 Socioeconomic Survey* conducted by the National Statistics Office, as cited in Trairatvorakul (1984); only calorie intake information is provided for various food groups; a calorie conversion rate of 3,500 calories per kilogram was used to compute rice consumption per kilogram.

^a Tercile in the case of Indonesia.

ing the same set of prices differ only in the activity levels necessary for earning that income. Energy requirements will be greater for the person engaged in the more active occupation. Under a reasonable set of assumptions (Bouis 1989a, 1990), the more active person will spend more for food than the less active person; more important, his/her diet will be more staple based because staples are relatively inexpensive sources of calories. If rural occupations require a greater energy expenditure than urban occupations, one would expect a priori to observe more staple consumption by rural populations.

Third, rice is cheaper to purchase in rural areas, in particular by rice producers themselves. Farmers who grow rice and consume out of own production avoid retailing and other marketing costs in staple purchases. Apart from greater risks associated with growing nonfood crops, such a cost saving may be an important additional incentive for semisubsistence farmers to grow staples. (See Bouis and Haddad 1990a, chaps. 4 and 7, for an analysis of this phenomenon for a specific group of farm households in the Philippines.)

In order to understand structural changes in demand behavior for rice over time in countries where a significant proportion of rice consumption comes from own production (all of the countries studied by IPG would qualify under these criteria at the start of the time-series data used, with the possible exception of Singapore), it is important to study three groups of consumers: (a) urban, (b) rural rice producers, and (c) rural nonrice producers. Thus, it is useful to write:

$$(1) \quad D_N = \theta_U D_U + \theta_{Rr} D_{Rr} + \theta_{Ro} D_{Ro},$$

where D is per capita consumption, θ is proportion of population, N is national total population, U is urban population, R is rural population, r is semisubsistence and commercial rice producers (these households may grow crops in addition to rice), o is producers of crops other than rice (these households grow no rice at all), and

$$(2) \quad \theta_u + \theta_{Rr} + \theta_{Ro} = 1.$$

Approaching analysis of national aggregate consumption in this way, it is conceivable that significant decreases in aggregate consumption could occur over time if consumption levels differed significantly such that, controlling for income,

$$(3) \quad D_U < D_{Ro} < D_{Rr}$$

and if there was significant rural to urban migration and/or rice production declined in importance in the rural sector. While increasing per capita incomes are usually associated with structural change in developing economies (i.e., rural to urban migration and a switch from subsistence to commercial agriculture), at some point these processes run their course (e.g., Japan and Taiwan). It then would be misleading to associate further increases in income with the same reduction in consumption of rice.

Correlations between Changes in Per Capita Rice Consumption and Structural Changes

Table 3 ranks the countries cited by IPG by percentage change in per capita rice consumption from 1961–65 to 1981–85.⁴ Also given in the table are percentage changes in rice production, agricultural gross domestic product, and total agricultural population, and change in percentage of the population which is urban.

The first relationship to note from table 3 is that rice production growth rates in Malaysia, Nepal, and Thailand (which IPG designate as Group I countries, experiencing substantial declines in per capita consumption of rice) were much lower than growth rates in agricultural gross domestic product in these countries. Rice production growth rates in these three countries were at or below the median as compared with rice production growth rates in other countries in South and Southeast Asia. Countries with the highest percentage increases in per capita rice consumption had the highest rice production growth rates, which tended to exceed growth rates for agricultural gross domestic product. Rice production became relatively more important within China and Indonesia, where the increases in per capita consumption of rice were highest.

Table 3 also indicates increased urbanization all over Asia. However, the trend in population densities in rural areas exhibited two distinct patterns as this urbanization occurred. Population densities in rural areas declined in Japan, South Korea, and Taiwan. Presumably as this occurred, rice farms increased in size, semisubsistence production gave way to commercial production, and marketed surplus as a percentage of total rice production greatly increased. These changes contrast with increased land pressures and production of rice on smaller operational units in several countries whose agricultural populations increased by 45% or more from the early 1960s to the mid-1980s. If yields had not increased so substantially in most of these countries, marketed surplus (as a percent of total production) likely would have fallen.

With the information in table 3 as background, consider the following implicit equation:

$$(4) \quad \% \Delta D_N = f(\% \Delta RCPRD - \% \Delta AGGDP, \% \Delta AGPOP, \Delta PCURB),$$

where Δ is change, $\% \Delta$ is percentage change, D_N is aggregate national per capita consumption of rice, $RCPRD$ is rice production, $AGGDP$ is agricultural gross domestic product, $AGPOP$ is agricultural population, and $PCURB$ is percent of total population which is urban. If $D_{Ro} < D_{Rr}$, then as rice becomes less important in total agricultural production, *ceteris paribus*, national aggregate consumption declines. Because data for D_{Ro} , D_{Rr} , θ_{Ro} , and θ_{Rr} are lacking, $\% \Delta RCPRD - \% \Delta AGGDP$ is a rough proxy (in con-

⁴ Singapore and Burma are excluded because of lack of data.

junction with $\% \Delta AGPOP$ discussed below) for the percentage change in the contribution of semisubsistence production of rice to total agricultural production. In the regression results presented in table 4, this variable is multiplied by the percent of the population which is rural at the beginning of the period, since the effect of $\% \Delta RCPRD - \% \Delta AGGDP$ on $\Delta \% D_N$ will be greater the larger is the rural sector.

$\% \Delta AGPOP$ is included as a control for farm size. *Ceteris paribus*, as farm size declines (as $\% \Delta AGPOP$ increases), there is a greater prevalence of low-income rural households producing rice for their subsistence needs, both to increase food security and to avoid paying marketing margins for their rice consumption. Finally, $\Delta PCURB$ controls for differences between urban and rural consumption of rice. If D_u

$< D_{ro}$, then the expected sign of the coefficient for $\Delta PCURB$ is negative. However, in most countries average urban incomes are higher than average rural incomes; if rice is not an inferior good, then controlling for production effects on consumption, the expected sign is positive.

The results of estimating (4) are shown in table 4. The rough-and-ready nature of the proxy variables used in the regression estimations, the small sample size, and the lack of variables which account for changes in prices, all provide admittedly compelling reasons for caution in interpreting the correlations shown in table 4. Still, the correlations are strong, have the expected signs, and explain much of the variance across countries. The positive coefficient on $\Delta PCURB$ suggests that higher income urban house-

holds do consume more rice than rural households, once production effects on consumption are controlled.

Conclusions

It is beyond the scope of this comment to provide conclusive evidence that the decline in rice consumption in some Asian countries (and increases in others) is largely the result of structural changes in income generation and not to the amount of income that is earned, although the two can be correlated over time. The main benefit from estimating (4) is to show that the aggregate country data at least do not contradict, indeed are very consistent with, two propositions that merit further research—first, rice consumption in Asia does not decline rapidly with income per se, and second, national per capita rice consumption levels have been and in many countries still are closely related to rice production relationships that determine marketed surplus (farm size, irrigation, and road infrastructure, adoption of modern technologies).

In countries where semisubsistence rice production is still important, aggregate national rice consumption may continue to decline as agriculture becomes more commercial and especially as rural population densities decline. However, predicting the existence and rate of such a decline will depend on a much better understanding of the effects of the commercialization process and of reduced work activity levels (which presumably accompany economic development) on demand for specific foods, and for staples in particular.

More specifically, after controlling for income, how much of the difference between urban and rural consumption (shown in table 2) can be explained by (a) generally lower food prices in rural areas, (b) lower implicit rice prices which rice producers pay for consumption of own-production, and (c) by higher work activity levels in rural areas? Are there factors related to expenditure survey techniques that lead to gross overestimates of rice consumption for rural consumers, as compared with urban consumers (Bouis and Haddad 1990b)?

Can supporting evidence be found that the substantial declines in per capita consumption of rice over time in Japan and Taiwan resulted from a decline in semisubsistence rice production? Why has rice consumption not fallen in South Korea, as apparently happened in Japan, Singapore, and Taiwan? Did these substantial declines in consumption in fact not occur in some instances? Are some of the time-series data used by IPG derived from unreliable production and stock information?⁵

⁵ The validity of the 222 kilograms per capita consumption of milled rice cited for Burma for 1981–85 can be questioned on a priori grounds. Such a level of consumption corresponds to a calorie availability of about 2,800 calories per adult equivalent per day, which is about 10% above the recommended intake for the Philippines from all foods. Similarly, the figure of 191 kilograms per capita for Thailand for 1961–65 is quite high.

Answers to these questions are crucial for planning investments for agricultural research and irrigation. Because of the substantial time lags in realizing investment benefits, if these investments are reduced or delayed because of overly pessimistic demand projections, rice prices may rise unnecessarily with adverse consequences for the poor in Asia, urban and rural, who are net consumers of rice.

Rice in Asia: Is It Becoming an Inferior Good? Reply

Shoichi Ito, E. Wesley F. Peterson, and Warren R. Grant

Given the prominence of rice in Asian economies as well as the importance of Asia for world rice markets, it is not surprising that the results we reported in our article (Ito, Peterson, and Grant) were somewhat controversial. We concluded that declining income elasticities of demand for rice in Asia mean that predictions based on conventional elasticity estimates are likely to overestimate total demand. Although the authors of the two comments reach their conclusions using very different approaches, they appear to agree that our predictions underestimate future rice demand in Asia. This debate is important because certain policy decisions in Asia, as well as in other nations exporting or importing rice, may depend on how actual Asian rice demand evolves. In our reply, we respond to each of the comments in turn.

Reply to Huang, David, and Duff

Huang, David, and Duff raise a number of issues concerning data and method. In particular, they argue for the following procedures: (a) use of private consumption expenditures expressed in a common currency rather than per capita gross domestic product (GDP) expressed in national currencies, (b) use of domestic price data instead of world price data, and (c) the use of prior information in specifying the ridge regression. Using these procedures, they reestimate our model and obtain results that differ from the results we reported. However, their results do not differ greatly from those we reported. While the income elasticities estimated by Huang, David, and Duff decline more slowly than those we estimated and remain positive in two countries where our estimates indicate that rice has become an inferior good, the general tendencies predicted in our study are replicated in theirs.

There will always be differences in elasticity estimates derived from different research approaches and data sets (Gardiner and Dixit). Choosing between two sets of estimates is complicated in this case because, due to the use of ridge regression, the diagnostic statistics associated with each model are not reliable. Although the estimated standard errors in our

model are substantially smaller relative to their corresponding coefficients than is the case for the model reported by Huang, David, and Duff, this cannot be taken as an indicator of statistical superiority because of the biases introduced by using ridge regression. Price has developed a formal procedure for comparing two models of this nature, but such a test requires more data, space, and time than we have available. However, the challenge to our results presented by Huang, David, and Duff is based critically on the procedural points they raise. In the absence of statistical indicators, an examination of the validity of these points is a reasonable way to approach the evaluation of their criticisms.

The first procedural point raised by Huang, David and Duff concerns the data series used to represent income. Huang, David, and Duff argue that per capita private consumption expenditure (PCE) is a better measure of income than gross domestic product (GDP) because it does not include government expenditure which, they suggest, is likely to grow more rapidly than the private consumption components of GDP. Although it may indeed be the case that, over time, a greater proportion of GDP is accounted for by the governments of these countries, this part of the argument is an empirical question for which the authors provide no support. If the change in composition of GDP is not great, it is likely that the two series will be highly correlated, so it makes little difference which is used. Correlation coefficients between PCE and GDP were computed for all the countries except Bangladesh, Nepal, the PRC, and Taiwan for which data were not available from the International Monetary Fund (IMF). These coefficients as well as the results of regressing PCE on GDP are shown in table 1. The results indicate that the two series are very highly correlated (most of the correlation coefficients are either 0.999 or 0.998), and we conclude that it probably makes little difference which series is chosen.

In addition to criticizing the data series chosen to represent the income variable, Huang, David, and Duff suggest that income should be expressed in a common currency rather than in individual national currencies. According to the authors, their income variable, *PCE*, is expressed "in real terms (deflated by consumer price index) . . . in US dollars converted by the purchasing power parity (PPP) exchange rate for 1980." The PPP exchange rate should account for relative inflation rates between the individual countries and the *numéraire* country, presumably the United

^a The regression coefficients are the slopes from equations with PCE as the dependent variable. The figures in parentheses are standard errors.

^b Correlation coefficient between PCE and GDP in each country.

States, so it is difficult to see why the income series should also be deflated by some unidentified consumer price index. In addition, the use of the PPP exchange rates introduces variables (e.g., the U.S. inflation rate) that may have little to do with domestic demand in these countries. The income variables used by Huang, David, and Duff may be appropriate for countries such as Singapore, where all of the rice consumed is imported. For the other countries where imports generally make up less than 10% of domestic consumption (except in Malaysia where they account for 20%), the distortions introduced by this conversion may be worse than the statistical problem signalled in their comment.

The second procedural point raised by Huang, David, and Duff concerns the price data. It is, of course, preferable to use domestic price data rather than world prices if domestic prices are accurately reported. The reason we chose to use world prices is that we were unable to locate reliable national price series for rice and wheat. Huang, David, and Duff apparently have access to such series, although they do not document their sources. The authors indicate that their domestic price series and the ratios they discuss in the text of their comment are taken from "individual country sources" (p. 4), none of which is cited in the references. Although government policies can drive a wedge between domestic and international prices, it is difficult to isolate the domestic

market completely from world market conditions. Even in Japan, with its highly protectionist rice policies, internal rice prices are not completely insulated from changes in world prices. The correlation coefficient between the Japanese government procurement price (deflated by the Japanese consumer price index) and the Thai rice export price converted to yen (also deflated by the Japanese consumer price index) and lagged one year is 0.76 over the period 1961–89 (based on data from Food Agency and IMF). This suggests that the use of world prices may not seriously undermine our results. Further, if the domestic prices obtained from individual country sources are not accurately reported, the statistical results could be worse than those based on the more reliable world price series taken as proxies for domestic prices.

The third procedural point raised by Huang, David, and Duff concerns the use of prior information in ridge regression. They suggest that the following criteria should be used in choosing the k -values for the ridge regression: (a) the k -values should be small; (b) they are expected to give rise to a negative coefficient for the inverse of the income variable; (c) the coefficients from the model should lead to elasticities that are close to the constant elasticities obtained from a double-log specification. The first criterion is not controversial. In specifying our model, we specified small k -values (0.00002, 0.05, and 0.1 compared with 0.002, 0.01, and 0.0005 in Huang, David, and Duff). With respect to the second criterion, we also expected the coefficients for the inverse-income variables to be negative in line with our expectation that income elasticities in Asia are declining as incomes increase, as we stated in the text. We did not constrain the coefficient estimates to be negative and, apparently, Huang, David, and Duff did not do so either because they report positive coefficients for the inverse-income variable in two countries, Bangladesh and South Korea. In terms of including the "prior information" embodied in the first two criteria suggested by Huang, David, and Duff, there does not appear to be much difference between the two models.

The third criterion really is not very useful. It does not provide a guide for determining what constitutes an estimate that is "not very far from the constant elasticities . . ." (p. 4). The justification for attaching particular weight to constant elasticity estimates appears to be statistical (see their footnote 5). There is no theoretical reason for taking elasticity estimates from a double-log specification as benchmarks for the empirical analysis. The double-log specification does not satisfy the adding-up condition of theoretical demand analysis and, thus, makes no more sense than some other specification as a reliable indicator of the order of magnitude of the elasticities (Phlips). The justification in footnote five would apply equally well to an ordinary linear model.

In addition, applying this criterion to the results presented in the authors' table 5 does not unambiguously favor the k -values they selected. For example, consider the estimates for 1975. Only four of the es-

estimated elasticities in the column under k^* are closer to the constant elasticity estimates than estimates recorded in other columns. Seven of the estimates based on a k -value of 0.00001 are closest to the constant elasticities, with one each in the other columns. In fact, out of thirty-nine possibilities in table 5, only twelve of the estimates in the k^* column are "better" in the sense of being closer to the constant elasticities. One wonders exactly how the "prior information" contained in the constant elasticities was used to select the preferred k -values.

The comment by Huang, David, and Duff is based primarily on these procedural points and a few unsupported assertions. We have responded to the procedural points and leave it to the reader to decide whether the criticisms of Huang, David, and Duff are telling. On the whole, their analysis appears to be a somewhat "ad hoc" attempt to generate outcomes consistent with certain preconceptions. For example, the authors argue that negative income elasticities are implausible in low income countries. This is an empirical issue, and it is misleading to assume at the outset that a commodity can never be an inferior good in low-income countries. Daly et al. reported a negative income elasticity for rice in rural Vietnam in 1973, a time when that region would certainly have qualified as "low income." Another example of an unsupported assertion is the suggestion by Huang, David, and Duff that income elasticities in Thailand can be "expected to become negative only sometime in the 1980s." According to their own estimates presented in their table 3, the Thai income elasticity became negative in 1967.

Finally, Huang, David, and Duff argue that, based on their results, the countries with negative income elasticities account for only 10% of Asian rice consumption. They speculate that income elasticities for rice in most Asian countries will remain positive throughout the 1990s and that rice demand in the region will remain strong. In another study (Peterson, Lan, and Ito), we obtained estimates indicating that the income elasticity of demand for rice in the People's Republic of China became negative in the early 1980s. The income and price data used in this study were from Chinese sources, and the analysis was based on time-series estimates of the log-inverse-log model. These results are not subject to any of the criticisms Huang, David, and Duff raise because the data meet all of their recommendations, ridge regression was not used, and the Chinese account for more than one-third of total world rice consumption.

Reply to Bouis

In the other comment, Bouis argues that changing patterns of rice consumption in Asia may be due primarily to structural changes in Asian economies, notably those related to rural migration and the commercialization of rice production. These results actually complement ours in that they provide insights into

the processes behind declining per capita rice consumption in some countries. Bouis's results appear to support his conclusion that aggregate declines in rice consumption may occur as "agriculture becomes more commercial and especially as rural population densities decline." This conclusion can be linked to our results if it is true that income increases in Asia are associated with agricultural commercialization and declines in rural population densities. While this association seems plausible, an empirical test is still needed. At any rate, Bouis's focus on country-specific explanations for aggregate changes is a useful contribution to the discussion of Asian rice demand.

Bouis does recognize some limitations in his analysis. We would add a few procedural and conceptual points to his list. In discussing rice consumption, Bouis relies primarily on expenditure data. Rice expenditure is not the same as rice consumption because different qualities of rice mean that there will be different prices at any given time. In Japan, for example, rice prices range from around 300 yen per kilogram to over 600 yen per kilogram depending on the quality (Ito, Wailes, and Cramer). Ito, Wailes, and Cramer have shown that higher-income consumers tend to purchase higher-quality rice rather than larger quantities. The figures in Bouis's table 1 do not reflect shifts of this nature, and his inferences concerning the quantities consumed by higher-income consumers may be misleading. Similar comments may apply to his second table depending on whether the quantities shown were obtained by dividing expenditures by average prices or whether data on quantities consumed were also collected in the expenditure surveys cited.

Bouis's empirical analysis is based on an equation relating changes in aggregate rice demand to a set of proxies that are supposed to measure changes in semisubsistence rice production and farm size, controlling for differences in rural and urban consumption. This equation does not appear to have a basis in economic theory because prices and incomes, variables normally associated with the theory of demand, are not included. Real retail rice prices are shown for most of the countries under discussion in table 2. In many cases these prices fell considerably between 1961 and 1981, a fact which may be important in accounting for consumption patterns. Even if one accepts Bouis's specification, it is not clear that the proxies used in the statistical exercise are good measures of the target variables. For example, the first variable is supposed to measure the "contribution of semisubsistence production of rice to total agricultural production." To measure this, however, Bouis uses total rice production and agricultural GDP normalized on the percentage of the population that was rural in 1961. This might make sense as a proxy if all changes in rice production took place on semisubsistence farms. This may be true in some countries but probably not in all of them.

In motivating his comment, Bouis suggests that we would explain changing consumption patterns by claiming that "urban incomes are higher and that higher

Table 2. Comparison of Real Retail Prices of Milled Rice in Asian Countries between 1961 and 1981

Country	1961 ^a	1981 ^b	Real Price of 1961 Rice ^c	Change ^d

income consumers prefer to substitute more preferred foods for rice." In fact, we make no claims with respect to urban incomes. Our study relates national consumption to national income, focusing on aggregate income elasticities of demand. Thus, Pitt's elasticity estimates for rural areas are not strictly comparable to ours. Rural and urban demand elasticities often differ, as we noted (see also Moon, KREI, and Daly et al.). Further, we would emphasize that our estimates, as in the case of any elasticity estimates, pertain to marginal changes, not the large change Bouis suggests in his thought experiment on Japanese consumption at the beginning of his comment.

reason to alter the overall conclusions we presented in our article. The results of our study on China (Peterson, Lan, and Ito) support and strengthen those conclusions, although we are more willing to defend the trends we identified in the two studies than the exact magnitude of the estimated income elasticities in specific countries at specific times. Bouis emphasizes the potential social costs of insufficient investment if future rice demand is underestimated. It is important to note that there would also be social costs if rice demand is overestimated and too much is invested in this sector at the expense of other economic activities.

[Received October 1990; no revision.]

Conclusion

The authors of both comments have raised interesting points. In the conclusion of our original article we commented on some of the limitations of the analysis. Huang, David, and Duff, and Bouis suggest other limitations and offer further recommendations for an improved understanding of Asian rice demand. Their contributions are useful in refining the issues related to this important topic and offering alternative visions of the changing markets for rice in Asia. After reflecting on their comments, however, we see no

The Efficiency of Alternative Policies for the EC's Common Agricultural Policy: Comment

Alison Burrell

In a recent article in this *Journal*, De Gorter and Meilke (DGM) compare the redistributive efficiency of agricultural price support policies under alternative assumptions about accompanying supply control measures. Using a long-run supply curve which is assumed invariant with respect to policy choice, DGM assess the consumer/taxpayer cost per ECU of total producer surplus under different policies and conclude that individual production quotas followed closely by a two-tier price policy are preferable to price reductions or a coresponsibility levy.

The main substance of this note is that DGM's failure to recognize the underlying structural problems of EC agriculture and to identify the true political target of income support measures renders their approach incapable of yielding a determinate ranking of these measures in terms of their medium-term efficiency and invalidates their policy recommendations.

EC agriculture still suffers from the problem of too many producers of inadequate economic size. In the mid-1980s, agricultural employment in EUR 12 was still over 8% of total civilian employment. About one-third of total agricultural labor input was used on the 38% of farms in the very small and small size groups (average size about 6 hectares), which produced only 8% of total output (Commission). This pattern holds for most individual outputs. In particular, 51% of all holdings growing cereals in 1985 in EUR 10¹ had less than 5 cereal hectares, and 80% less than 10 hectares (Eurostat).

Paradoxically, the structural weakness of European agriculture is both the product of past policy and a continuing political constraint on attempts to reduce CAP price support. Despite the increased emphasis on structural policies for withdrawing surplus resources from agriculture (early retirement, dairy cessation, land set-aside, land conversion to nonagricultural use), there is still considerable scope for the capture of economies of size.

Clearly, medium-term structural evolution in EC agriculture is endogenous with respect to the choice of policy. It follows that an appropriate analytical framework for comparing medium-term policy outcomes must explicitly recognize differential policy-induced shifts in the supply curve. Moreover, DGM's device of standardizing the outcomes of alternative

policies by holding constant the aggregate producer surplus for the sector may be theoretically acceptable, but it is unsatisfactory as a basis for policy recommendations in the EC context, where the political target of income support is the return to farm-owned assets of the marginal full-time farmer or per agricultural work unit. DGM's approach ignores the fact that policy-induced changes in the number of producers and the distribution of total supply over producers will differ between policies, resulting in different values of the political target for a given value of aggregate producer surplus.

Initially, a quota scheme freezes structural change. Its medium-term impact depends on the arrangements for quota transfer. The greater the constraints placed on the free transfer of quota between producers, the more slowly cost-reducing structural change can proceed. Attempts to counter this effect by increasingly expensive producer buy-out programs followed by quota redistribution to existing producers result in additional program costs which should be acknowledged in the comparative costing of policies.

On the other hand, if quota is freely marketable, structural change is more rapid than in the absence of quota markets, permitting greater improvements in the efficiency of resource use but at the expense of policy efficiency. Over time, an increasing proportion of income support is capitalized into the value of quota.² As quota sellers are bought out, they take capital out of the sector. Established producers or new entrants who buy quota do so from owned or borrowed capital. If the capital is borrowed, the claim on assets in the sector becomes more diffuse and some income support intended for producers is creamed off by lending institutions. If the capital is supplied by the farmer, this extra capital still has an opportunity cost and must earn a return comparable with alternative uses. In either case, the residual return to the traditional farmer-owned assets of land, labor, management, and productive capital (excluding quota) is squeezed. This can be visualized as an upward displacement of the medium-term supply curve in DGM's figure 1.

By contrast, both the two-tier price and the price reduction policies lower the price on marginal units and on some or all intramarginal units and so provide

Alison Burrell is a senior lecturer in agricultural economics, Wye College, University of London.

¹ EC less the two most recent entrants, Spain and Portugal.

² For instance, there has been significant, capitalization of income support into milk quota values in many EC member states since the scheme began in 1984, with quota prices reflecting the high marginal net return to expansion due to economies of size.

a greater stimulus to structural rationalization. Falling costs cause a more rapid downward displacement of the aggregate supply curve, so that over time the relative redistributive efficiency of these policies (as defined by DGM) changes. At the same time, producer numbers decline. It is the net effect of these changes which determines producer surplus per agricultural labor unit, according to which these alternatives should be ranked. It is impossible to determine the ranking from an analysis in which structural change is ignored. However, it seems unlikely on a priori grounds that the quota alternative would be optimal.

This view assumes that for the EC cereal sector and EC agriculture generally (a) there are significant potential size economies and (b) it is economically justified and politically realistic to ignore the costs to individuals of structural change. Regarding (a), we cite the poor size distribution of production referred to above, the existence of size-dependent technologies involving greater mechanization and specialization of management, and the copious literature (discussed recently by Castle, for instance) on the role of increasing size in the adoption of new technology.

It can also be argued that the economic and political climate is increasingly favorable to proposition (b). The age distribution in EC farming is much more heavily weighted toward the over-50 age groups than in the industrial or service sectors (Commission), and labor recruitment problems resulting from demographic changes are forecast in these sectors for the 1990s. More information is now available about the declining role of farming in the economics of many farm families. For instance, although three-quarters of holdings in the Federal Republic of Germany grow cereals, about half those in the field crops/mixed crops/crops and livestock categories have other gainful activity apart from farming (Eurostat). All this evidence suggests that the perceived social and political costs of structural rationalization may be lower now than at any time in the history of the CAP.

DGM's comparison of the terms-of-trade effects of these policies is also questionable. With exogenous world excess demand for EC exports, the terms-of-trade benefits are greatest for the quota program because it involves the largest reduction in the EC exportable surplus. However, these benefits may be short-lived. For example, in markets where world prices have been undermined by the export of EC surpluses (most notably dairy products and sugar) some of the world's least-cost exporting countries have curbed their export capacity in order to avoid further deterioration of the terms of trade against them. Short-run terms-of-trade benefits enjoyed by the EC following the introduction of a quota scheme could fall away as the volume of world trade is partly restored by these countries. Once again, it is a question of the medium-term endogeneity of supply conditions with respect to EC policy choice, but this time in other trading countries. Are these medium-term adjust-

ments incorporated (via lagged prices or otherwise) into DGM's function for world excess demand for EC exports?

Finally, two practical points should be stressed. First, DGM note that the dual role of wheat as both intermediate input (feed) and final product (food) would create problems in implementing a two-price scheme and hence their final recommendation of a quota scheme for this sector. However, under a quota system there would be the same tendency for feed wheat user prices to equal marginal production cost because cereal farmers with livestock production would use their own wheat (at cost) rather than buying it at the higher market price.³ Second, the administrative difficulty of imposing the enforcing individual quotas in a sector where half of all holdings (about 2.5 million farms in EUR 10) grow cereals (Eurostat) is probably insuperable.⁴

In conclusion, the long-term problems of EC agriculture must ultimately be solved by structural rationalization. DGM ignore the medium-term endogeneity of structural change and fail to incorporate into their model the structural impact of each policy. The current willingness of EC policy makers to increase their reliance on structural measures and on the targeting of assistance to particular groups of producers while at the same time taking a stronger line on support prices marks a step toward the decoupling of income support from market management and the renewal of the link between marginal supply and market conditions. A quota program is a backward move on this policy continuum. DGM's conclusions, skillfully argued though they are, are based on a false identity between the long-run properties of their model and the long-run realities of CAP reform.

⁴ Compare milk: only about 27% of EC farms have dairy herds and, given the nature of the product, the administrative framework for monitoring individual supplies already existed prior to quotas.

The Efficiency of Alternative Policies for the EC's Common Agricultural Policy: Reply

Harry de Gorter and Karl D. Meilke

Burrell argues that our welfare evaluations of alternative policy options considered by the European Community (EC) for the Common Agricultural Policy (CAP) fail to recognize policy-induced shifts in the supply curve. Burrell concludes that our approach is therefore "incapable of yielding a determinate ranking" and hence "invalidates" our policy recommendations. Although we analyzed four policy mechanisms and showed both theoretically and empirically that a production quota, under some circumstances, is inferior to a two-price plan, Burrell determines unequivocally that a quota is an inferior instrument.

Her conclusion is based on several arguments. First, nontransferable quotas induce economic inefficiency. This is true; but at no time in our original paper did we recommend that quotas, or any of the other three instruments for that matter, be implemented in an inefficient manner. We assumed transferable quotas.

A comprehensive evaluation of alternative implementation methods for each of the four policy instruments was beyond the scope of our paper. Nevertheless, we question Burrell's assertion that quotas will necessarily be implemented in a more inefficient manner than, for example, a two-price plan. To motivate the problem, consider Canada's production quota scheme for milk and compare it to the two-price plan used in the United States. Nontransferability of quotas between provinces in Canada induces deadweight costs additional to those calculated in our paper. Similar costs are also incurred currently in the EC with nontransferable milk quotas between countries.¹ However, Class I minimum prices in the United States are set in relation to Eau Claire, Wisconsin, so that the most deficit region in the United States is self-sufficient in milk production. This induces additional social resource costs resulting from distorted regional production patterns akin to those induced by nontransferable quotas in Canada and the EC (Public Hearing on Federal Milk Marketing Orders).² Indeed, the U.S. two-price plan has another ineffi-

ciency associated with it: farmers' production decisions are determined by the blend price rather than the lower Class II price. These inefficiencies of the U.S. program may well induce more additional social costs than a nontransferable quota scheme.³

Interestingly, a production quota scheme superimposed on a two-price plan can improve efficiency. The United Dairymen of Arizona, representing all dairy farmers in Arizona, unilaterally instituted production quotas for Class I milk in the 1970s (de Gorter and Schmitz). Any milk produced in excess of this quota received the Class II price. This effectively eliminated the blend pricing scheme facing Arizona's farmers and hence reduced output. Because the federal government of the United States fixes the Class I and II prices to consumers, the latter's welfare was unaffected. The welfare of Arizona farmers increased because the high Class I price was not diluted by the lower Class II price, and costs of overproducing at the blend price were not incurred. U.S. taxpayers benefitted because production was lower, and given fixed prices to consumers, resulting in lower costs in removing Class II milk products from the market. Production quotas were therefore a Pareto-superior move!⁴

The open-ended price support system of the EC with unlimited export restitutions also has inefficiencies that are ignored by Burrell and in our original paper. Since the late 1960s, producer prices in the EC have been anything but "common" as a result of green rates and member country subsidies which have resulted in the renationalization of agricultural subsidization (Runge and von Witzke). The incremental costs to a country of these subsidies are often less than the incremental benefits net of the increase in its share of the budget burden induced by this production increase. We call this phenomenon easy riding on the CAP, rather than free riding because it costs a little to gain. As a result, the social costs of the CAP are higher; but these costs could be avoided with a production quota scheme that would limit the production effects of member country subsidies.

The above discussion illustrates the impossibility

Harry de Gorter is an assistant professor, Department of Agricultural Economics, Cornell University; Karl Meilke is a professor, Department of Agricultural Economics and Agribusiness, University of Guelph.

¹ Milk quotas are transferable between farms in most provinces in Canada just like they are in most EC countries.

² Rucker, Thurman, and Sumner recently analyzed the welfare costs of nontransferability of tobacco and peanut quotas across county lines and found the costs to be minimal.

³ Another inefficiency induced by the blend pricing scheme in the United States which would not have occurred with quotas was the unnecessary conversion of grade B milk production enterprises to grade A enterprise.

⁴ The irony is that the quotas were disbanded after being deemed unconstitutional in a lawsuit brought forward by the Department of Justice. See de Gorter and Schmitz for an interesting discussion.

of arguing categorically that quotas are an inferior instrument because of nontransferability.

Second, Burrell argues that even transferable quotas induce a leftward shift in the supply curve. Farmers, she argues, bid up the price of quotas such that the returns are comparable to other enterprises, causing an upward displacement in the medium-term supply curve. This is true, but the capitalization of rents would also occur with the other instruments evaluated in our paper. Rents in the two-price plan would have to be allocated with marketing quotas or certificates of some kind, generating a value just like production quotas. An open-ended price support scheme with or without a co-responsibility levy will result in the values of other fixed assets like land bid up so that the returns to farming will be comparable with alternative uses of capital. If land purchases are undertaken with borrowed capital, then the same amount of "creaming" of income support by financial institutions will occur. There is nothing unique to quotas in this entire discussion by Burrell.⁵

A further criticism of our paper made by Burrell is that aggregate producer welfare is not the appropriate political target. We acknowledge that an improved and more refined policy performance measure other than aggregate producer surplus is desirable. Burrell argues that the true political target is returns to farm-owned assets of marginal full-time farmers or producer surplus per unit labor in agriculture.⁶ She states that EC agriculture suffers from too many farmers of inadequate size and that politicians ignore costs of adjustment. Indeed, Burrell implies that the price support schemes of the CAP are intended to facilitate structural rationalization of European agriculture. We question the views taken by Burrell on this issue. Indeed, we would argue the opposite in that the political rationale of price support schemes is to compensate farmers for the costs of adjustment and to slow the migration of farmers out of farming and rural areas in general. Politicians, therefore, neither ignore adjustment costs nor feel there are too many farmers. Surely, if structural adjustment was the primary motivation for the CAP, a more efficient instrument than open-ended price supports could have

been found. Quotas have the further advantage of allowing governments to achieve political efficiency more easily by being able to target benefits of price supports to specific farmers. Ironically, Burrell finds it paradoxical that the structural weakness of European agriculture is both a product of the CAP and of political constraints. This would not be a paradox if one understood the true political goals of the EC.⁷

Burrell also questions our discussion on the terms-of-trade effects of these policies and asks whether the endogeneity of supply conditions with respect to EC policy in other trading countries is incorporated in our analysis. We borrowed the excess demand elasticities from the work of Tyers and Anderson. These elasticities were estimated by using information on the domestic supply and demand elasticities in the most important trading nations, the shares of production and consumption that are traded, and the price transmission elasticities. The latter include the effects of policy in other countries by summarizing how domestic prices (and policy instruments) set by governments respond to changes in world market conditions. In this sense adjustments by other countries to EC policy is incorporated in our analysis by these price transmission elasticities. We do, however, question Burrell's assertion that the rest of the world curbs export capacity in response to any deterioration of the terms of trade resulting from EC export surplus disposal schemes. The U.S. response to increased EC export restitutions on wheat in the 1980s was to lower the loan rate and institute the export enhancement program. This U.S. response lowers the world price rather than increases it as argued by Burrell.

Finally, Burrell makes two practical points. The first point is that our welfare measure is incorrect because, under a quota system, cereal farmers with livestock would value their own feed at cost rather than at the high price support. This is absolutely false. Our measure of producer welfare is an economic one that includes opportunity costs. Selling grain to your own livestock enterprise does not preclude the economic benefits of the price support from being captured. Any farmer that feeds his own feed under a quota scheme for cereals incurs the opportunity cost of not selling the cereal on the market at the high price support. The second practical point raised involves the administrative costs of enforcing quotas with so many farms. This may be a legitimate point, but we have two qualifications. First, if it is so complex, how is it that the Canadian Wheat Board manages marketing quotas and how does the United States

⁵ Footnote 2 in Burrell states that the price of quota values for milk in the EC reflect high marginal net returns to expansion due to economies of size. This is purely speculative. All farms receiving quotas in 1984 were required to reduce production from their historical levels. All farms therefore experienced marginal returns higher than marginal costs. Just because some farms have lower marginal costs and are able to purchase quotas in expanding output does not imply a change in the economies of size. Indeed, how can one tell that the largest farms have the lowest marginal costs at the initial level of quota? Perhaps smaller than the largest farms bought quota, and so fewer large farms now exist. Besides, one can show that positive quota values exist in an industry exhibiting constant returns to scale.

⁶ Quotas are a farm-owned asset and so returns are realized by those farmers that politicians have targeted in issuing quotas to them in the first place.

⁷ Burrell argues that more farmers would remain in farming with transferable production quotas compared to other instruments attaining the same level of producer surplus. This is not correct, as quotas typically result in lower levels of output relative to other options and transferable quotas ensure production will occur by the most efficient number and size of firms. Therefore, it is quite possible that the number of farms declines more with production quotas relative to other policy instruments.

administer base acreage? Second, it is not obvious that quotas are any more difficult to administer than, say, a two-price plan or a co-responsibility levy. Both are difficult and potentially messy to administer. Nevertheless, we admit that our welfare analysis, like most, ignores administration costs.

In conclusion, Burrell argues that, because we ignore endogeneity of structural change, our policy recommendations are based on a false identity between the properties of our model and the realities of CAP reform. From the discussion above, it is obvious that Burrell has failed in developing a logically consistent analytical and empirical framework to incorporate the structural impact of EC policy alternatives. Although such an analysis was beyond the scope of our original paper, we do not wish to deter the profession from analyzing such issues. Examples of work in this vein are the landmark paper by Krueger in analyzing the differential impact of import tariffs versus quotas, and de Gorter and Fisher who analyze rent seeking in a dynamic analysis of how (non-quota!) policy in the United States induces additional deadweight losses beyond those captured in the traditional static analysis.⁸

Books Reviewed

Atkin, Michael. *Agricultural Commodity Markets: A Guide to Futures Trading*. London: Routledge, 1989, 249 pp., \$79.95.

Until the late 1970s, agricultural economists had a virtual monopoly on books dealing with the futures markets. With the development of financial and options contracts, a host of books were generated by authors who are not agricultural economists, although a recent book by Leuthold et al., *The Theory and Practice of Futures Markets*, bucks the trend. Many books include agricultural commodities as only one segment of the futures market complex, for example *Understanding Futures Markets*, by Kolb. Other books focus on specific nonagricultural futures contracts, the Loosigian books, *Interest Rate Futures* and *Foreign Exchange Futures*, are good examples. The current approach is not to examine specific types of futures contracts at all, but to present theory and analytical techniques useful to advanced students and practitioners. Examples of this genre include *Option Pricing* by Jarrow and Rudd and *Commodities Trading* by Seidel and Ginsberg.

The book under consideration, *Agricultural Commodity Markets: A Guide to Futures Trading*, seems to be a return to a bygone era, a descriptive book focusing only on agricultural commodity futures markets. In the author's words, it is a book "aimed at a broad audience of students, economists, traders and the general public" (p. xv). The book is intended to fill the gap between highly technical publications and the "get-rich-quick trading commodities" books.

Organizationally, the book is sectioned into two parts. The first part gives the reader an overview of the structure and operations of the agricultural commodities futures markets. In the second part of the book, the author examines the major agricultural commodities including grains, oilseeds, livestock and meat, coffee, cotton, sugar, and cocoa.

The book is well written, although the use of British rather than American spelling in some places is slightly disconcerting. More disturbing is the use of British terms, such as contango for carrying charge, backwardation for inverse carrying charge, highly geared for leveraged and maize for corn. The author does explain the difference in terminology. The first part of the book on the structure and operations of futures markets is rather brief, although the chapter on options is especially well written. The discussion of major agricultural commodities is the usual description of factors affecting supply and demand conditions for each commodity. The treatment of hedging takes only slightly more than three pages, although it is mentioned in passing in several other places. In contrast, an entire chapter is devoted to speculation. A major drawback in both chapters, throughout the book for that matter, is the lack of examples.

Atkin's last chapter, "The Future of Futures," is

the best in the book. He traces the development of futures markets, including the introduction of financial futures contracts, to the present time and then describes his vision of the future for futures trading. He envisions the development of a global market for futures trading and points out the need for futures trading centers rivaling Chicago to be located in the Pacific Rim and in Europe. Atkin also points out that "the potential for increased developing country usage of futures markets is huge, given their importance in world agricultural trade" (p. 222). Intriguing is his discussion of the development of computer-based, electronic trading systems which would allow 24-hour trading around the world. Because of the difficulties which would arise if live floor trading were replaced with totally computerized markets, Atkin foresees "a novel combination of the two types of trading . . ." (p. 216).

In summary, *Agricultural Commodity Markets* would not make a good teaching text for the simple reason that it lacks examples, problems, and end-of-chapter questions that would aid student understanding. Most economists today would expect more depth and breadth in a book on the futures markets. Beginning traders and the general public interested only in agricultural futures would find the book useful, although potential hedgers would be very much disappointed.

Becker, Tilman. *Die Weizenexportpolitik der Europäischen Gemeinschaft* (Wheat Export Policy of the European Community). Agrarwirtschaft Special Study No. 121. Frankfurt am Main, Federal Republic of Germany: Alfred

Strothe Publishers, 1989, 242 pp., 44.5 DM (approx. \$27.81).

Since the Food Security Act of 1985, the United States has pursued a two-pronged agricultural export policy with respect to the European Community (EC). It has employed the Export Enhancement Program (EEP) to increase U.S. market share in EC-contested markets while encouraging multilateral trade liberalization through the General Agreement on Tariffs and Trade (GATT). Because the focus of the competition between the United States and the EC has been the world wheat market, European studies of this market are of obvious interest to an American audience.

Becker's study has two objectives: to analyze the EC grain export policy and to suggest decision criteria for efficient export administration. These objectives are pursued in five chapters: introduction, the EC as grain exporter, the world wheat market, the EC wheat export policy, and summary.

From Becker's perspective, EC grain policy faces a conflict between the stable domestic demand and rising production. EC grain yields rose at a rate of 3.3% annually between 1967 and 1984 and are expected to continue increasing until by the year 2000 the EC-12 may have to retire up to 30% of its current production area.

Because the EC grain programs are likely to remain expensive, how can export subsidy (restitution) expenses be minimized? Becker analyzes EC restitution costs for wheat and barley as an example. Using a Lagrangian framework, Becker concludes that EC expenses are minimized when the ratio of marginal changes in wheat and barley restitution costs are equal to the ratio of wheat and barley feeding values. Becker reports that the EC appears to have used this decision criterion in 1983 and 1984 but deviated from it in 1985 to avoid confrontation with the United States.

He goes on to characterize the world wheat market as oligopolistic, with the United States providing price leadership. Grain storage is the key to his understanding of the wheat market because it allows exporters to practice seasonal price discrimination. By manipulating stocks and export subsidies, exporters can force the elasticity of export demand toward 1 and maximize export earnings. U.S. price support policy reinforces this result, Becker argues, when target prices are set in the elastic portion and loan rates are set in the inelastic portion of the demand curve.

The author presents a graphical analysis of supply and demand conditions in the subsidized and non-subsidized export markets and concludes that export subsidies are rational only when revenue gains from price increases in nonsubsidized markets offset costs. This occurs when the supply curve in the nonsubsidized market is inelastic. Consequently, unless world supplies are constrained, export subsidies are likely to result in a net welfare loss.

Becker concludes by addressing two questions: when and where should the EC export?

When? Becker simulates seasonal EC export levels using a profit function for wheat storage. Studying both budget cost minimization and profit maximization, optimal marketings are shown to occur earlier in the marketing season as storage costs, interest costs, wheat prices, and the elasticity of demand rise. Becker concludes that EC welfare gains could increase 10 million ECU by using export licenses to select the optimal timing of export marketings. The same result is obtained when private firms time marketings according to his framework. Optimal timing of wheat export licenses in 1987/88 could reportedly have saved the EC up to 100 million ECU. Becker notes that cost minimization and profit maximization yield differing seasonal export recommendations.

Where? In analyzing the relative performance of exporters in the nine EC export marketing zones, Becker develops a probabilistic model of trade flows based on world origin and destination statistics. He argues that the EC should concentrate on import markets in which the competition from other exporters is unstable; that is, in markets where importers are price sensitive rather than exhibiting loyalty to one supplier. EC subsidy expenses should furthermore rise in markets with high elasticity of demand and fall in markets with low elasticity of demand. In this manner, marginal changes in restitution costs are equalized across all importers and budget expenses are minimized. This has the effect of increasing restitutions in distant markets and decreasing restitutions in local markets.

Becker more than adequately accomplishes the objectives set forth for his work. His analysis of EC export operations and policy is thorough, and his outline of decision criteria for program administrators is convincing. The study's chief weakness stems, in part, from its pragmatic nature. Becker's research is preoccupied with "second-best" policy prescriptions—prescriptions that increase the efficiency of existing programs. He recognizes that export subsidies are suboptimal in the current market environment and that land retirement cannot ultimately be avoided. He does not, however, employ these insights to widen the scope of this research. Consequently, it is clear that his research results will be of most interest to individuals who are administrators of EC wheat programs. Advocates of trade liberalization are less likely to find his research useful.

Farm Credit Administration

Coombs, H. C. *The Return of Scarcity: Strategies for an Economic Future*. Cambridge, UK: Cambridge University Press, 1990, x + 171 pp., \$39.50, \$17.95 paper.

This book is discomfiting. Its essence is that population growth, technological change, and free markets confronting finite material resources are leading the world on the path to perdition. Of course, its theme is not new, nor are its arguments and evidence par-

ticularly original. But it packages the message in such a way that even the most ardent worshiper of free markets has his/her faith shaken a little by the end of the book.

The author has had a distinguished career in academia, government, and community service in Australia. He is a former governor of the Reserve Bank and chancellor of the Australian National University. For the past twenty years, he has been a leader in developing policies to promote the arts and policies to assist Australia's aboriginal peoples. Now, at eighty-four years old, he is a visiting fellow of the Centre for Resource and Environmental Studies at the Australian National University.

This book is a compilation of essays written over the past two decades. The essays reflect the author's "anxiety as a private citizen and member of the academic community about the threat to our society" arising from the interaction of economic and ecological problems. As might be expected, there is considerable repetition of ideas in the nine essays. Also, there is consistency in his essays, which is somewhat surprising with worldwide changes in political and economic systems over the past twenty years.

According to Coombs, market economies produce a vast array of goods, and by standard measures, GNP and accumulated wealth, western societies' economic welfare is increasing. But the end products of the system—the lifestyles of its members, their cultural experiences, their personal relationships, and their physical environment—are worsening and are likely to continue to do so.

Population growth, increased demand for consumer goods, increased scarcity of basic resources, increased use of labor-saving technology, and the emergence of a world economy continually change the operation of the economic system. First, they increase rents for owners of scarce resources, owners of technology, or those with specialized knowledge. Labor is rewarded less, and it is placed in an increasingly unfavorable bargaining position. The result is a continuing redistribution of income toward owners and away from workers and providers of services. Increasing shares of income go to transnational corporations, which tend to dominate the development of economies. There is increasing difficulty in satisfying the expectations of adequate and improving real incomes for most in society. Expanding population, technological innovations, and environmental degradation reduce practical alternatives for a simpler lifestyle. Private property closes off opportunities for low-cost access to the amenities of nature. Environment quality deteriorates as technological change results in polluted air and water. Species are threatened with their very survival. Quality of life may improve for the few fortunate, but for the vast majority, quality of life deteriorates even though their consumption of consumer goods may increase.

Coombs solutions mostly rely on heavy handed government intervention. Some of this intervention would change economic incentives. A resource tax

or graduated royalties would be levied against users of scarce resources. Differential pricing for electricity, petroleum, and water would result in higher prices for heavier users. A tax rebate would be used to encourage savings and investment. Advertising would be thwarted by limiting income tax deductibility of advertising expenses. But his principle strategies are selected government ownership or regulation. Scarce minerals, forests, seas, soils, vegetation, and wildlife would be collectively owned. Title to these scarce resources would be vested in an authority independent of corporate and political control. License for their use would be granted to those assuring their conservation. Monopoly rents would be collected and distributed to subsidize resource conservation research, to finance community facilities designed to improve the quality of life, and to provide all citizens a "national dividend." Land users including farmers would submit land use management plans and have them approved by a conservation authority. Similarly, all enterprises involved in resource industries would comply with approved resource and environmental plans. The government would use unemployed labor to protect and improve the environment. Inheritance taxes would confiscate most decedents' property except the family home, personal possessions, family-operated farms, and other individually operated enterprises.

Those who see the "workings of the market as expression of divine wisdom" will be irritated by this book. Indeed, they probably will dismiss it after a few pages. After all, resource substitution, technological change, and increasing productivity will mitigate the impacts of increasingly scarce resources. Societies do not need the heavy hand of government to adapt. In fact, market mechanisms provide for quicker and more efficient adaptation to resource scarcity than do administrative solutions. I imagine that Coombs would concur with this judgment. He does not question the efficiency of the market or its ability to respond to scarcity. His argument is that standard economic measures of performance are faulty. They do not value quality of life—income distribution, environmental quality, stocks of finite mineral resources, amenities of nature, opportunities to choose simpler lifestyles, the involvement of individuals in groups, and the fulfillment individuals receive in their lives. His view is that quality of life is deteriorating even though GNP is increasing and that only collective action to cause structural change in our economic system can keep this deterioration from accelerating.

D. Lynn Forster
Ohio State University

Demissie, Ejiguu. *Small-Scale Agriculture in America: Race, Economics, and the Future*, 1st ed. Boulder CO: Westview Press, 1990, x + 135 pp., \$20.00.

This book accomplishes what few others, if any, have attempted, an economic assessment of small-scale

farms (gross sales less than \$40,000). This assessment is vital because small-scale farms represent the majority of agricultural enterprises in the United States. Moreover, the author provides an analysis of both black and white small-scale farmers. The primary objective of the book is to describe the history and current status of small-scale farm operators in the United States and to provide background information that can be used by policy makers and program administrators as they attempt to halt further decline of small-scale farms. Demissie notes that the book is written for audiences in the agricultural and nonagricultural communities, students of agriculture, as well as citizens who have concerns about small-scale agriculture and rural development.

The book is divided into seven chapters. The introductory chapter begins with the author's description of the structural changes (farm size and number) that have occurred in the agricultural sector this century. This chapter clearly shows that "most of the decline in the number of farms has been in the small-scale farm category" (p. 3).

In chapter 2, the general characteristics and trends for small-scale farms and farm operators are addressed. The author provides a "profile of small-scale farms with respect to their agricultural production, resource use and control, farm asset holding, types of enterprises, and farm production expenses" (p. 8). Furthermore, he compares and contrasts the profiles over time and by farm size, thus showing the rapid decline of farms, especially among blacks.

Chapter 3, entitled "Characteristics and Composition of Black Farm Operators and Their Farms," examines some of the same characteristics addressed in chapter 2 but discusses differences between black and white farm operators. It presents an historical view of these farms as well as their current status. The chapter concludes with a short discussion of the historical development of 1890 land-grant institutions (black land-grant colleges and universities) and their role in assisting small-scale farmers, especially black farmers.

Chapter 4 gives an economic assessment of the farm and farm operators by examining their past and present financial conditions. The chapter looks at trends in farm income, assets and debts, surmising that their financial problems are symptoms of the structural changes. The financial comparison was based on farm-sales class, thus depicting the poor financial condition of small-scale farmers. This chapter further showed that many small-scale farmers do not obtain financing from traditional lending institutions but from internal savings.

Chapter 5 discusses some of the social, economic, and political constraints that have negatively impacted the survival of small-scale farm operation in the United States. The factors addressed included resource endowment, education, technology, marketing, management and information, government policies and programs, and sociological constraints.

In chapter 6, "Small-Scale Agricultural and Rural

Development," the author attempts to show that the loss of small-scale farms has had a substantial impact on both the viability of rural communities as well as the fabric of rural life. Although this discussion is interesting, it lacks depth. Very few data are used to support the discussion.

Chapter 7 provides a brief discussion about the various programs (technology, management, marketing, education, credit, and government) that can be useful in solving problems faced by small-scale farmers. The author places particular emphasis on the enhancement of research and extension efforts to eliminate the decline of small-scale farms.

The material contained in this book, basically taken from the *Census of Agriculture*, can contribute to an enlightened dialogue about the plight of small-scale farmers, especially black operators. It is an excellent resource book that can be used to increase public awareness of the issues, concerns, and possible public policies that could affect the future survival of small-scale farmers. Moreover, although much of this material is not new, having the information in this condensed version makes it valuable. The book falls short in several areas, however. It is not well integrated, there are some redundant materials and poor sentence structure, especially in the first two chapters. Because it is written for the average citizen, the book may not have the sophistication that graduate students and professionals in the field expect. Last, the future, as depicted in the book's title is not adequately addressed. Notwithstanding, the book makes a substantial contribution to a very important segment of our population, small-scale farmers.

Donald R. McDowell
North Carolina A&T University

Ferguson, Roy C., II. *Managing for Profit in Commercial Agriculture*. Englewood Cliffs NJ: Prentice-Hall, 1990, xvii + 208 pp., \$47.20.

This book attempts to deal with both the Canadian and U.S. situation, but the Canadian references are an obvious afterthought. The book has several weaknesses but is useful for farm management professionals and students as a reference source. The first and most glaring weakness is that the task of proper analysis of the farm business is made to look too complicated for most farm business managers. The calculations and the acronyms used in the calculations are often confusing. The author has made little attempt to clarify and simplify the text. The amount of detail recommended leaves the impression that many managers will need to hire professional expertise to help manage their businesses.

The book begins by discussing the farm business problems of the past ten to fifteen years and the role that weak financial accounting and analysis procedures played in these problems. The author argues that most of these problems could have been avoided by following his system of financial analysis. He correctly stresses that agriculture is no different from any

other form of business and therefore should be subject to the same strict borrowing, accounting, and analysis rules as other businesses. He also argues that detailed accounting information with as much accuracy as possible should be emphasized. In chapter 4, he presents the recommended financial documentation needed for agriculture and includes examples of balance sheets, operating statements, cash flow statements, and loan documentation requirements. The amount of detail recommended is very commendable but probably impossible to achieve economically on many Canadian farms, even if the owners wanted to.

Chapters 5, 6, and 7 present the "Ferguson System of Financial Analysis," and chapter 8 includes a number of cases that apply the system. Fourteen "signals of financial health" are presented in chapter 5, with emphasis that this is the minimum for proper financial analysis and that the reduction to fourteen already represents a significant compromise. The full "Ferguson System" of thirty-six financial ratios and indices are presented in chapter 7. The author emphasizes that no single ratio or small group of ratios should be used on their own or with less than four-to-six years of detailed and accurate data to back them up. These data requirements both in duration and detail effectively eliminate most Canadian farms.

The author goes on to designate a series of critical values or guidelines for the various ratios and indices dependent on enterprise type, such as crops, hogs, cow/calf, beef feedlot, poultry, and dairy. These guidelines are given as precise measurements but are backed up only by the "Ferguson Group experience" rather than with any quantitative study proving them to be legitimate leading indicators of farm financial troubles. In addition, the ratios should be adjusted by a rather complicated process for changes in such items as percentage of total revenue and proportionate sales from the various enterprise types referred to above. Chapter 6 presents examples of how to calculate these adjusted guideline levels. Chapter 8 presents a number of cases to illustrate the use of the "Ferguson System." The cases are quite detailed, and the text describing the analysis is hard to follow. I could not help but get the impression that with detail supplied in the cases, the answers for the most part were quite clear by studying the exhibits and did not need the full application of the "Ferguson System" to solve. In fact the "Ferguson System" application seemed to add to the confusion.

Chapter 9 is entitled "Eight Fatal Flaws Leading to Problem Debt" and is a very good summary of some important considerations in farm credit management. Chapter 10 deals with farmland purchase economics. The return to land are calculated for a number of crops, including grassland, land quality, and locations. The author concludes that land seldom if ever pays for itself and that farm managers should seriously consider renting a portion of their land.

Chapter 11 is entitled "Capital Development" and deals with the subject of obtaining capital from lenders and investors. The author presents a number of

hints that will ensure the lender's thoughtful consideration of the loan proposal. The chapter also deals with ways and means of attracting investor capital and suggests the completion of a 200- to 400-page complete business plan. I am not aware of too many farmers who could complete such a plan without considerable professional help.

Chapter 12 deals with the understanding and effective implementation of five disciplinary principles called "Management Stardom's 5 Points." The first is knowing the business you are in, which includes the key characteristics and requirements of commercial agriculture and the need for a strong management information system. Next is the requirement to maintain a correct internal business structure with respect to the use of capital and monitoring performance. Third, eliminate price risk for both inputs and outputs through futures markets and forward contracts. The fourth point is to maintain efficient operations by reducing cost, eliminating crisis management, and monitoring performance. The final point is the use of effective people from management and ownership to employees to professional counsel.

The final chapter is an epilogue that warns that the recent financial disasters could easily be repeated if farmers do not become significantly more business conscious and adopt the approach presented in the book.

In summary, the book is a good addition to the library of anyone interested in farm business management. The frequent references to the author's system and company and the need for professional help eliminate it, in my opinion, from use as a university text.

William J. Brown
University of Saskatchewan

Hancock, Graham. *Lords of Poverty: The Power, Prestige, and Corruption of the International Aid Business*. New York: The Atlantic Monthly Press, 1989, 234 pp., \$17.95.

Western nations provide some \$60 billion of foreign aid annually to developing or Third World countries. Despite this huge transfer of funds from the West, Hancock argues that developing countries would be better off without it. The author's assessment of foreign aid is based on his many years of foreign experience as a reporter for *The Economist*. In his words, foreign "aid is not bad . . . because it is sometimes misused, corrupt or crass; rather, it is inherently bad, bad to the bone, and utterly beyond reform" (p. 183). To illustrate the ill effects of foreign aid, Hancock attacks the "rich and powerful bureaucracies . . . that administer the West's aid and then deliver it to the poor of the Third World . . ." (p. xv).

Hancock's book is divided into six chapters, with each chapter attacking specific aid bureaucracies or employees of the aid industry. Chapter 1, titled "Masters of Disasters," sets the stage, and it provides

many examples of development gone awry. Included among these are examples of charitable organizations spending most monies intended for developing countries, food shipments never reaching their intended destinations, donated food being unfit for human or animal consumption, field employees of the aid industry refusing to do field or site assessments of food and medicine needs during disasters or crises, and western experts placing evangelism ahead of assistance. Chapter 2 attacks the World Bank, the International Monetary Fund, and other multilateral organizations such as the European Economic Community and the United Nations. The alleged sins of these organizations include wasteful expenditures of \$10 million for annual meetings of the World Bank and International Monetary fund; structural adjustment loans (SAL) causing massive increases in unemployment in Chile, substantial increases in child malnutrition in Peru, and significant increases in infant mortality rates in Brazil.

Chapter 3, "The Aristocracy of Mercy," attacks the many organizations of the United Nations and the many individuals who profit from these and other aid-related organizations. Hancock states that most workers in the aid industry admit they are attracted to the high salaries and the opportunity to stash away small fortunes. An example includes a UN worker who states, "I won't try to pretend that I took this job out of idealism . . . the money was very important to me." (p. 79). The monetary rewards of "aid industry" employment also are evident as one considers the fact that another employee of the United Nations privileged aristocracy "was receiving a subsidy of \$10,661 per month towards the cost of his three-bedroom apartment . . . close to UN headquarters" (p. 93). Moreover, the Food and Agriculture Organization arm of the United Nations has "750 individuals whose pensionable remuneration ranges from \$70,000 to \$120,000 a year . . ." (p. 93). Hancock argues that such remunerations are not paid because they are necessary to attract the best and most competent employees. On the contrary, "at every level of the multilateral agencies, maladjusted, inadequate, incompetent individuals are to be found clinging tenaciously to highly paid jobs . . . betraying the world's poor in whose name they have been appointed" (p. 99).

Chapter 4, "The Midas Touch," attacks foreign "experts" for planning and implementing projects in the Third World on the basis of information gained from runways and highways. Hancock states that "major development projects absorbing vast sums of Western tax-payers' money and affecting the lives of billions of people in the Third World for years to come are routinely conceived, planned, supervised and appraised on the basis of visits that are equally brief, hurried and superficial" (p. 121). He concludes that such projects occur because the World Bank and its partners in development are "out of touch with poor people, and with the day-to-day realities of their lives . . ." (p. 151).

Hancock's attack in chapter 5 is directed at the dis-

proportionate share of "aid" expenditures that are spent in industrialized countries. He questions the logic of an American aid program that is intended "to meet the basic needs of poor people in developing countries" (p. 160) . . . when "70 cents out of every dollar of American assistance to the Third World never actually leave the United States" (p. 156). Similarly, he questions the Third World development efforts of the World Bank when 70% of its funds are "spent on goods and services from the rich industrialized countries" (p. 159). Worse still, purchased goods and services from industrialized nations are often marked-up and of low quality. He further argues that the introduction of food commodities, such as wheat, does a disservice to the development process because it relegates local commodities, such as corn, to an inferior status.

The final chapter summarizes the previous five but also provides additional evidence about the ill effects of foreign aid. A point of focus for the author relates to financial flows between Third World countries and wealthy industrialized nations. Measures of financial flows show that Third World nations are net donors to industrialized nations, raising the question of who is helping whom?

Any reader of this book, whether employed inside or outside the aid industry, will probably agree that the author provides evidence that there have been many ill-conceived, mismanaged, and wasteful projects undertaken in Third World countries. Individuals inside the aid industry, and even some outside, will undoubtedly conclude that the author has provided a biased and unfair assessment of the aid industry, however. Despite the billions of dollars that have been wasted, clearly there are some success stories related to foreign aid. Improved education, better transportation, telephone communication, and electricity generation are benefits that most observers attribute to foreign aid. Perhaps net financial flows between the rich and poor are not a relevant measure of foreign assistance. A more meaningful measure might be the enhanced economic ability of poor countries to make financial transfers as a result of previous foreign assistance.

Additionally, perhaps foreign assistance should not be evaluated by the extent to which poor people are involved in project planning but the extent to which they benefit from project outcomes. In this regard, economic development does seem suspect. Even in the United States where poverty is less pressing compared with the Third World, evidence suggests that the poor people today are worse off than they were ten years ago. Indeed, there are individuals who readily admit that the war on poverty and other aid programs to help the poor have been a failure in the United States. If poor people are made worse off by poverty programs in industrialized nations where the problems are less severe, then one has to wonder how the aid industry can deal with these problems in the Third World where problems are more severe.

This book illustrates that it is easier to write about

the problems of poverty than it is to solve them. Nevertheless, the book provides an assessment of foreign aid that is sure to challenge the actions and thought patterns of aid workers. It is an inexpensive book that can be purchased with a fraction of one's hardship allowance.

Harl, Neil E. *The Farm Debt Crisis of the 1980s*.

Ames: Iowa State University Press, 1990, xix + 305 pp., \$24.95.

This book is part of the Henry A. Wallace Series on Agricultural History and Rural Studies, a series designed to explore the many aspects of agricultural and rural life within historical perspectives. The author was prompted to write the book "by a strong belief that the lessons learned in the farm debt crisis of the 1980s should be identified and memorialized to assure ready access on the occasion of the next major economic downturn in agriculture" (p. 269). The book thus represents a history of one participant's personal odyssey through the farm debt crisis period of the past decade. The book was conceived as history, not economics, and should, in fairness, be judged as such. Harl's intended audience is future policy makers, who will learn his view of appropriate intervention in the event of future such crises.

The author portrays himself as a visionary whose role was to arouse the nation to recognize what he feels was the irresponsibility of the Economic Recovery Tax Act of 1981 and in his opinion the tragedy it produced in the agricultural sector. He champions public sector intervention to address this tragedy since, in his view, it was a result of bad public policy foisted on an innocent and powerless agricultural sector. Thus, beyond a broad synopsis of the author's opinion as to the causes of the crisis and the general innocence of farmers and (less so) their lenders for the calamity they faced, the major themes of the book are the need for massive public sector intervention and the recalcitrance of federal-level public officials in acknowledging and addressing this need. In particular, the intervention Harl advocated was widespread farm debt restructuring and warehousing of farmland acquired because of bad loans in a federally chartered Agricultural Credit Corporation (ACC) until times improved and farmland values recovered.

The volume is divided into ten chapters dealing with different aspects of the debt crisis. Chapter 1 describes the public policies that Harl feels inexorably led to the crisis, while chapter 2 presents his evidence on the innocence of farmers and the slowness with which all concerned realized the magnitude of their plight. Chapter 3 describes the need for and chronicles Harl's proposals for debt restructuring. Chapter 4 relates the growing problems of the Farm Credit System (FCS) and the author's attempts to convince some of the FCS leadership that their system was vul-

nerable to crippling loan quality problems. Chapters 5 and 6 address proposals for further federal involvement, heel dragging in Washington, and "the obvious gap between reality and what Washington seemed to believe was reality" (p. 164). Chapter 7 lauds state efforts to address the farm debt crisis. Chapter 8 discusses the impacts of the farm debt crisis on local businesses, and chapter 9 addresses at length the influence of the media during the farm debt crisis. In keeping with Harl's purpose for writing this book alluded to earlier, the final chapter (10) summarizes his twelve lessons for posterity. However, the author makes no attempt to develop the relative importance of or logic behind these lessons, nor do all of them directly follow from preceding chapters.

Of most interest to academic readers will be chapters 1, 2, and 10 as a source of testable hypotheses for future scholarly research. Portions of chapters 3 through 8 will hold interest for some readers concerned with their particular focuses, although they will pay the price of wading through a chronologically disorganized and ponderous account. Harl relies heavily on references to or quotations from the popular press and trade publications, many of which add only peripheral detail and tedium.

In the initial chapters, Harl presents his view that the farm debt crisis arose as the result of three federal policies: (a) the policies pursued over at least five successive administrations with respect to inflation, (b) the abrupt action taken by the Federal Reserve Board beginning in October 1979 to reduce the rate of inflation, and (c) the massive experiment implicit in the large tax cuts of 1981. He holds these policies directly responsible for a strong dollar, lower exports, high interest rates, falling land values, and sizable farm loan defaults. In contrast, the author repeatedly argues that farmers affected by debt problems during the decade were neither greedy, nor poor managers, nor speculators. Despite the rapid build-up in farm debt in the 1970s, he is grudging in assessing farmers much responsibility. The most he admits is that a substantial portion of the farmers in deep financial difficulty were striving to reach the minimum point on the average cost curve "in perhaps less time than would have been prudent, at least viewed with 20/20 hindsight" (p. 70). Because the federal government is viewed as initiating the forces leading to the severe farm sector debt trauma and farmers were generally innocent, Harl suggests that such assistance was economically justified whenever the total costs and consequences of intervention were less than the expected costs and consequences of failure to intervene. He never explicitly identifies these costs, quantifies them, or discusses on what basis they should be distributed among lenders, taxpayers, and borrowers.

The book fails to address the debt situation in U.S. agriculture as it developed in the 1970s and to analyze the sector's economic health as it went into the 1980s. During the 1970-80 period, at the same time the GNP deflator increased 104.0%, U.S. per acre

farmland values grew 277.9% (369.4% in Iowa). Total farm debt expanded 228.8% (291.4% through 1983) despite considerable excess capacity and reliance on federal subsidies. Even Farmers Home Administration lending grew 504.6% during the 1970s. This lender of last resort loaned \$11.9 billion (\$19.2 billion for 1970–82) alone under various types of emergency loan programs during a decade that was deemed a prosperous one for agriculture.

Harl recognizes that the problem during the 1980s was too much farm debt concentrated among a subset of farmers. He then recommends some expensive solutions. He estimated that his debt restructuring proposal would cost the federal government \$20 to \$30 billion if adopted, and the tab for the ACC would have been up to \$10 billion (pp. 74, 152). The reviewers feel one problem with the ACC concept is that stabilization programs need to be in place *ex ante*; they do not work *ex post*. Nor do they work if the asset prices have moved to a lower equilibrium based on economic fundamentals rather than overshooting. By the time Harl proposed the ACC in late November 1984—early 1985, U.S. farmland values already had declined about half of the amount they ultimately fell (in Iowa about 45% of the ultimate 60.7% slide had already happened).

A major shortcoming of the book is its questionable perspective and lack of objective analysis. In this vein chapter 7, "States to the Rescue," deals with state involvement in the farm debt crisis. This is misleading, juxtaposed after two contentious chapters indicating federal inaction. State credit program subsidies, while significant, are small compared to those associated with federal farm programs. For example, in 1987 and 1988, state credit subsidies were roughly 2% of federal credit program subsidies to farmers. There is a neglect of the linkages among the major federal agricultural programs throughout the book and the fact that the federal support to agriculture during the 1980s was massive. Net CCC outlays to farmers, for instance, during the 1980–90 period totaled \$140.3 billion. Direct government payments alone to Iowa farmers during 1980–89 totaled \$8.47 billion, or about \$3,000 for every Iowan, or \$81,500 for every Iowa farm existing at the end of the decade. Federal policy makers felt, given the massive level of support, that new large specialized credit programs, such as the ACC plan, were too expensive and created perverse incentives for farm decision makers. Federal assistance tended to take the form of income rather than credit programs, hence helping all farmers and avoiding the equity issues of who should and should not receive help.

This book is a parochial and often strident memoir by a major player in the farm debt policy debates of the 1980s. While it may be of interest to some readers for that reason, serious scholars of the crisis will not find this to be an analytical or balanced view of the 1980s farm debt crisis. There remains a need for a workmanlike, scholarly analysis of the period including the economic status of the sector prior to the

1980s, the causal factors of the crisis, the effectiveness of and interrelationships among credit and other policies, and the status of the farm sector by the end of the decade.

Morse, George W., ed. *The Retention and Expansion of Existing Businesses: Theory and Practice in Business Visitation Programs*. Ames: Iowa State University Press, 1990, xvii + 195 pp., \$21.95.

Morse and six collaborators wrote this short book which describes the theoretical foundations, educational programs, and practical applications of the business retention and expansion visitation program (R&E), a local economic development technique which was first tried in the 1960s. The book is designed to serve as a basic reference for state development officials, local practitioners of local economic development, cooperative extension, and community economics academicians wishing to start state-level educational and technical assistance programs. According to the authors, their goal "is to stimulate local economic development by helping existing businesses increase their sales and employment through a combination of programs that not only increase these firms' competitiveness but also improve the community's quality of life."

R&E programs have gained considerable popularity in the 1980s. Unlike the informal, unstructured predecessor programs used by communities in the 1960s and 1970s, current R&E programs are more sophisticated and structured. They blend applied research with public relations and focus on "immediate action for resolving individual firm problems and long-term improving the communities' overall business climate and the competitiveness of local firms." This book provides the first in-depth analysis of these new, highly structured R&E visitation programs. Most of them operate out of land grant universities, but a few are operated by state governments and utilities.

The authors outline a multiple goal approach for R&E programs based upon their experience and research primarily in the state of Ohio, where these programs have been used most extensively. Part I, *The Theoretical Foundations of R&E Visitation Programs*, presents a conceptual model for the R&E visitation program and describes the impact of existing firms on regional growth. In chapter 1, Morse defines R&E visitation programs and provides a conceptual model. He argues that R&E visitation is more than a public relations program, more than an attempt to help firms move out of the past, and more than improved firm efficiency. In chapter 2, Miller provides empirical evidence contrasting the impact of existing firms on a community's economy with the

impact of new firms. His findings support earlier research that existing firms have greater impact on local economic development than new firms. Part II, Educational Programs, outlines the methods and objectives of the educational/technical assistance programs provided to communities starting new R&E visitation programs. In chapter 3, Otto, Morse, and Hagey review the status of current R&E programs and conclude that most states now recognize the importance of working with existing businesses to stimulate economic development, but few have developed training programs to facilitate the process. In chapter 4, Morse and Hagey present a detailed outline of the fifteen steps involved in conducting a local R&E visitation program based on their experience in Ohio.

In chapter 5, Morse points out the importance of supplementing primary data gathered from the visitation program with secondary data. He notes that R&E visitation data are much more meaningful "when studied in the context of national and regional economic and demographic changes, common industrial location factors, and the availability of state and federal assistance for economic development." Chapter 6, written by Rohrer and Morse, addresses the question, "How can needed information be provided efficiently and effectively to local volunteer teams?" In their opinion, this is best accomplished by presenting the Economic Development Teleconference Series to communities. The importance of the final report and some potential applications of the information gained are explained in chapter 7.

Part III of the book, Successful Local R&E Visitation Programs, outlines the structure of successful local programs in five states. Chapter 8 describes the major types of benefits in R&E programs, and chapters 9 and 10 list impacts of the R&E program in two rural counties in Ohio. Chapter 11 reports McLaughlin's research on an Ohio R&E program during its actual implementation. In chapter 12, Bentley draws on the extensive research done on plant closings and preventing layoffs by Hansen and Bentley to answer the question, "What do you do if the R&E program fails to prevent a plant closure or downsizing in the community?" Several assistance strategies are described, and the importance of having the assistance of a neutral, third-party facilitator or catalyst is stressed. Several appendices are provided that contain copies of the forms used in the Ohio R&E program.

The Retention and Expansion of Existing Businesses is a concise, well-written book which describes the process and usefulness of R&E visitation programs. Practitioners of the development craft will benefit from reading this book and applying some of the ideas it contains. This development approach emphasizes the importance of helping existing firms instead of spending time and resources trying to "steal" firms from other communities and states. Equally important, its focus on the R&E programs represents a new, forward-looking activity for land grant university extension services rather than continuing to de-

vote scarce resources to traditional but anachronistic activities. Unfortunately, many land grant universities are investing only token resources in these newer, more important programs.

Perhaps the biggest weaknesses of the R&E approach are its complex process and the substantial external training and technical assistance needed to make it successful. One suspects that few R&E programs outside Ohio measure up to the high standards set out in the book. Heavy dependence on volunteers and a lack of training and close supervision often lead to superficial studies and little follow-up.

The usefulness and application of this book can be strengthened by exploring the relationships and linkages which can and should be developed by university extension or other R&E staff with other players in the economic development arena to ensure concrete R&E results beyond a final banquet or community meeting. In some states it appears that R&E efforts are being carried out in isolation and are not fully integrated with other development agencies and groups in the community or even with other units on a university campus. Equally serious, R&E programs may be treated as a fad or a one-shot affair, soon to be discarded as development or extension administrators seek a newer, more glamorous panacea.

By describing the R&E visitation program, this book provides development professionals and community leaders with useful information and insights about another tool to use in the never-ending battle of trying to maintain economically healthy communities.

Moyer, H. Wayne and Timothy E. Josling. *Agricultural Policy Reform: Policy and Process in the EC and the USA*. Ames: Iowa State University Press, 1990, xx + 235 pp., \$27.95.

Moyer and Josling have produced an important text for those interested in policy formation. Their analysis of the problems of decision making in the EC and the United States is insightful and thought provoking. Their book is not so much about "Agriculture Policy Reform" as it is about the "politics and process" that prevent reform or perhaps retard the evolutionary process of policy reform.

In their introduction, they define reform as "a significant shift in policy direction, usually involving changes in instruments, arising from general dissatisfaction with the current operation of the policy" (p. xviii). They admit to the subjectivity of this definition and qualify it by reiterating that reform implies a significant shift in policy.

In part 1, Moyer and Josling review a variety of public choice and operational policy models as a preliminary exercise to the development and presentation of their "Process Schematic Approach" (p. 13) which they base on earlier work by Petit. The models reviewed provide some insight into the decision process, but each is inadequate as a model of agricultural policy reform because of the underlying assumptions

of the model. Rational choice models rely on a calculating central national actor. Public choice analysis assumes the maximization of egotistic utility subject to constraints. In the organizational process paradigm, the best predictor of what an organization will do today is what it did yesterday. The partisan mutual adjustment model assumes that policy is created through bargaining and consensus building.

Graduate students doing required reading should read part 1 carefully, otherwise you may safely skip to either part 2 "Agricultural Reform in the European Community," or part 3, "Agricultural Reform in the United States," to begin reading. If you desire, these sections may be read in reverse order because they are independent analyses of the policy processes in the EC and the United States. An occasional referral to the schematic in table 1.1 or a quick skim of part 1 is all that is required to follow either analysis.

Moyer and Josling hypothesize that: (a) initiative for reform must come from high-level central decision makers, (b) legislative actors would almost never initiate reform, (c) bureaucratic actors are not likely to be in the vanguard of reform, (d) a budget crisis provides the most potent stimulus to change, (e) the normal agricultural policy process will probably not make the necessary reforms, and (f) the process will change by broadening the range of participants or by shifting the decision locus. These hypotheses are not so much tested in the analysis as they are supported by anecdotal evidence in the chronology of policy development for the 1980s. In the end, it is difficult to determine the distinction between hypotheses, pre-conceptions, and conclusions.

Their schematic makes explicit a procedural outline, but it does not really help one identify the absolute or relative importance of the actors and procedures in the policy process. How one weighs the input from various actors remains unclear, and the importance of individual personalities is not really discussed in the Moyer-Josling analysis. Pitting a high-level somewhat naive reform-oriented ideologue against an entrenched group of rent seekers will not likely produce a compromise that will result in change. Yet, rent seekers will accommodate to change if the outcome remains ambiguous enough to convince a majority that they have nothing to lose and possibly something to gain. Or change might occur if rent seekers perceive that they will be worse off if they do nothing.

One is tempted to argue with some of the details of the Moyer-Josling analysis, especially when they say that farm bills are first formulated in the executive branch and are delicately balanced. However, they refute their own statement by pointing out that both farm bills presented by the Reagan administration were dead on arrival when they reached the Hill. In the final analysis neither the 1981 or 1985 acts bore any relationship to the administration proposals. They do not comment on the 1990 act because the book was published prior to its enactment. Perhaps the most significant lapse in the book is the authors' failure to recognize the significance of the policy change in the

1985 act which bases nonrecourse loan rates on a percentage of past prices. Income support is thus shifted from price enhancement to direct payments. And this shifts the burden from consumers to taxpayer and allows a relatively easy assessment of where the transfers go.

Moyer and Josling rely heavily on work by Petit and Bonnen to support their analysis, and one would be well advised to read these references for insight into the Moyer-Josling hypotheses. However, one need not accept either the Bonnen or Petit arguments to appreciate the outstanding chronological summary and analysis of the policy decision process in the European Community and in the United States in the decade of the 1980s.

The book leaves one somewhat unclear about how a general dissatisfaction with the operation of policy is discovered. And, it is ambiguous about criteria for measuring reform. What is it that is perceived as a policy failure that needs reform? Must reform constitute a move away from government action or is it a somewhat more efficient application of a program?

They conclude that "without a crisis it appears that comprehensive change is impossible" (p. 219). They suggest that reform occurs only in response to crisis which may be an excessive accumulation of stocks, larger and highly visible transfers to producers, external shocks including changes in exchange rates, shifts in export demand or, most important, a budget crisis. Although somewhat pessimistic in their conclusions, Moyer and Josling may, in light of the recent GATT round, be close to the mark regarding the opportunities and options for changing agricultural policies in the United States and the European Community.

Pasour, E. C., Jr. *Agriculture and the State: Market Processes and Bureaucracy*. The Independent Institute. New York: Holmes and Meier, 1990, 258 pp., \$39.95.

Agriculture and the State is a readable and comprehensive discussion of U.S. government programs that relate to agriculture. Pasour defines these programs

broadly to encompass not only commodity and food programs but also international trade, crop insurance, credit, conservation, taxation, research, and extension. Each chapter outlines the program and usually includes a simple economic graph understandable to intermediate economics students. The book could be successfully adopted for use in an undergraduate policy class or to supplement a graduate policy class. While the book reads like a text, including summaries at the end of each chapter, general readers can manage the book. Those readers who lack the skill to read the graphics can easily skim these sections without much loss in content; they will find the explorations of policies uniformly understandable throughout the book.

Pasour presents the entire book within a consistent set of arguments: agriculture programs have failed to achieve their purposes, government failure is at least as prevalent as market failure, and, almost without exclusion, private action is preferable to public action. As Pasour states in his preface in the book:

There are two quite different explanations of U.S. farm programs: the "public interest" and income redistribution. The "public interest" approach, which holds that U.S. farm programs benefit the public at large, represents the conventional wisdom in agricultural policy texts. In this book, in contrast, it is assumed that current programs are better explained by income redistribution. That is, it is assumed here that the persistence of and increased expenditures on farm programs can be traced to the success of agricultural interests in using governmental power to transfer income from taxpayers and consumers to farmers, owners of land and other farm assets, government employees, and agribusiness firms that benefit from current farm policies.—(pages xix and xx)

Pasour sustains this argument even with the more difficult cases of food distribution, conservation, public research, and extension. With respect to food programs, Pasour emphasizes implementation difficul-

ties: "There are formidable information and incentive problems inherent in food-stamp, school-lunch and other programs having means tests" (p. 157). With respect to conservation, he emphasizes the appropriateness of private solutions: "When transactions costs, incentive costs, and information costs are taken into account, there is little if any basis for thinking that an increased role of government in protecting land and soil resources is warranted" (p. 212). With respect to public agriculture research, he advocates private funding while criticizing as faulty those studies which conclude that public funding yields high rates of return: "When these 'government failure' problems are taken into account, it will be found that governments usually can best encourage research investment by defining and enforcing property rights so that privately funded research can be profitably undertaken" (p. 225). With respect to extension, Pasour argues that educational activities tend to be mainly private goods: "The public-goods rationale is less and less valid as one moves from basic science to the development and extension of new technology" (p. 219).

The basis for all of these conclusions lies in Pasour's demand that to merely find the market outcome wanting in terms of some objective is not enough; one must show that the government program—as it actually operates in real-world conditions—is better. His arguments are skillful and particularly challenging to strong believers in the wisdom of public action. These believers could sharpen their own analysis by a careful reading of (and sparring with) the arguments of Pasour. However, Pasour does not address opposing arguments in depth; the novice reader will not be exposed to alternative views of the role of government nor to more sympathetic assessments of existing government programs. *Agriculture and The State* is an unapologetic and well-written argument to limit the role of government in all aspects of agriculture.

Marketed Surplus Under Risk: Do Peasants Agree with Sandmo?

Israel Finkelshtain and James A. Chalfant

Using a newly defined notion of aversion to income risk, the behavior of the marketed-surplus producer under price risk is characterized. Unlike the familiar case first examined by Sandmo, output depends on both ordinal preferences for goods and on risk attitudes. Conditions are found that yield an output level under risk that is smaller than under certainty. If these conditions do not hold, both risk and risk aversion may have a positive effect on output. Implications for econometric studies of risk attitudes are considered and illustrated with an example. Finally, we examine the effect of uncertainty on the peasant's long-run equilibrium.

Key words: marketed surplus, peasant households, production under multivariate risk.

Agricultural economists have devoted considerable effort to studying production decisions by farmers in developing countries. Essential to this effort is a thorough understanding of the role of risk in peasants' production decisions. Important insights into this role of risk are provided by the literature on firms' behavior under risk. Perhaps the most influential paper in this area is by Sandmo, who established that a risk-averse firm facing output-price risk produces less output than a risk-neutral firm. Sandmo and the numerous studies that followed made use of the expected utility hypothesis, combined with an assumption that utility depends on only one random variable—the level of final wealth. Other risks affecting utility must be presumed absent or to have no effect on the behavior under study.

An important characteristic of the agricultural peasant household is the consumption of a portion of its own farm product (e.g., Haessel; Renkow; Toquero, Duff, Anden-Lacsina, and Hayami). Unlike the familiar case studied by Sandmo, when subject to output price risk, such a "marketed-surplus" household faces multivariate risk because the price of one of its con-

sumption goods is also random.¹ Thus, the profits risk affecting wealth cannot be modeled in isolation from other risks. As a consequence, a risk-averse household may no longer choose to produce below the profit-maximizing level of output when the price is random.

The literature (e.g., Roe and Graham-Tomasi) has emphasized that maximization of utility defined on wealth alone is not adequate to describe choices under risk in agricultural households. Anderson, Dillon, and Hardaker (p. 76) asserted that "money is not everything; and the consequences of many decision problems are . . . not well represented in terms of only a single attribute such as monetary gain or loss." Wolf (p. 2) observed that "peasants run a household, not a business concern." Similarly, Ellis (p. 102) proposed that "the interaction of consumption and production within the household causes a unique form of decision making which sets peasants apart from any other kind of production unit. . . ." Restrictions can be found that imply separability between production and consumption decisions. However, Fabella, Pope, and Finkelshtain offer examples showing that strong restrictions must be imposed on preferences in two-period models or in cases of multiattribute objective functions. Therefore, one must take explicit account of the process by which

Giannini Foundation Paper No. 964.

Financial support from the Giannini Foundation and the Kinamon Foundation, Faculty of Agriculture, Hebrew University of Jerusalem is gratefully acknowledged.

The authors wish to thank Jock Anderson and Offer Kella for valuable suggestions and comments. Any remaining errors are the responsibility of the authors.

¹ Another example of multivariate risk was examined by Herath, Hardaker, and Anderson, in the context of rice production in Sri Lanka in the presence of yield risk. They considered the varietal choice problem when utility depends on both income and subsistence rice consumption.

profits produce utility, through household consumption decisions, in modeling peasants' production decisions.²

These aspects of household behavior are examined below by combining Sandmo's model with the marketed-surplus literature and by utilizing an alternative to the univariate notion of aversion to risk. Following that, the implications for empirical studies of risk attitudes are explored and the long-run entry/exit decision of the household is described. Finally, we examine the potential for expanding the results to include additional sources of risk.

Peasant Behavior Under Price Risk

Virtually all studies of behavior under risk assume that the producer maximizes the expected value of a utility function defined only over income or final wealth. Aversion to risk in this single argument is measured by the curvature of the utility function, the Arrow-Pratt measure of risk-aversion. To model households facing risks in other arguments of the utility function requires a more general objective function and an alternative definition of aversion to risk. These tasks are taken up in this section.

The Household's Objective Function

We assume that the household is engaged in the production of a food crop (x). Consumption decisions concern leisure (l), a portion of the farm output (m), and an aggregate market good (z), representing the consumption of all other goods. Output and leisure are chosen prior to the realization of prices, while consumption goods are chosen in the harvest period when prices are known. The prices of m and z are denoted by p and q and the wage rate is w .

We assume that the household makes consumption and production choices to maximize the expected value of a utility function U defined over z , m , and l :

$$\max_{m,z,x,l} E[U(z, m, l)],$$

² The fact that such households have limited access to insurance or capital markets makes it especially important to examine the effects of the entire set of risks they face. Of course, the same comments apply to any agricultural household, but the problem seems most acute for low-income, marketed-surplus producers. Higher income farmers are less likely to be consuming part of their output, and the other risks they face are less likely to be correlated with the price of their output.

subject to

$$pm + qz + wl = y(x),$$

where y denotes full income. Because the optimal consumption plans may be revised *ex post*, the *ex ante* decision involves only l and x . Substituting the *ex post* optimal plans for m and z into U leads to the variable indirect utility function $V(y, l, p, q)$. Epstein established its duality to U . Hence, the above problem is equivalent to

$$\max_{x \geq 0, l \geq 0} E[V(y, l, p, q)].$$

In the univariate case where only y is random, V can be reduced to the familiar objective function defined on income or final wealth alone. However, if goods' prices are unknown at the time output is chosen, even under flexibility of consumption choices, their joint distribution is likely to affect output.

Epstein showed that the variable indirect utility function is increasing in y and homogenous of degree zero in y , p , and q . Accordingly, the market good will represent a *numéraire*, so q is normalized to be 1 and other monetary variables are measured relative to q . The real wage rate and the prices of other inputs are assumed to be known when the production and labor supply decisions are made. Thus, we concentrate on risks in the relative price of the food crop and in real income, both of which depend on the random variable p .

Using the notion of full income, total income is the sum of initial wealth, labor income $(T - l)w$, and farm profits given by

$$\pi = p \cdot x - c(x).$$

Here, T is total time endowment of the household and c is the cost function. Any fixed costs are assumed to be contained in c . Output is assumed nonstochastic.³ By the additional assumption that the input prices are known, $c(x)$ is deterministic.

An Alternative Risk Premium

Pratt's risk premium measures the maximum amount that an individual would pay to avoid

³ This assumption is not essential but simplifies the analysis and allows comparison with Sandmo's model. The main results hold under more general forms of stochastic profits, provided, of course, that p remains random.

income risk when nothing else is random. In terms of the current model, it is defined as S_p in

$$EV(l, y, \bar{p}) = V(l, \bar{y} - S_p, \bar{p}),$$

where the \bar{p} subscript indicates that the price of m is fixed at its mean. If the price of the portion of output consumed at home remained random, with only income stabilized, Pratt's risk premium would not necessarily measure the willingness to pay for income insurance. The risk premium appropriate for such a situation must be defined as the maximum amount that the individual would pay to avoid income risk when p remains random.⁴

$$EV(l, y, p) = EV(l, \bar{y} - S, p).$$

The interpretation of the modified risk premium S is analogous to that of the regular Pratt risk premium in the traditional univariate model, which appears as a special case, when the consumption price p is fixed at its mean.

This can be illustrated for small risks by a Taylor approximation of the equation that defines S , a derivation of which is given in an appendix, available upon request. Assume that the producer faces uncertainty about income and the price of one consumption good. For small risks, the risk premium is given by

$$S = -\frac{1}{2} \sigma_{yy} \frac{V_{yy}}{V_y} - \sigma_{yp} \frac{V_{yp}}{V_y},$$

where subscripts on V denote partial derivatives, σ_{yy} is the variance of total income, σ_{yp} is the covariance between total income and p , and the partial derivatives are evaluated at (l, \bar{y}, \bar{p}) . The first term in the above expression is Pratt's risk premium, the maximum amount that the producer is willing to pay to stabilize income when prices are fixed. The second term captures the value (or cost) associated with the stochastic interaction between the consumption price and his income. If this covariation did not affect utility (because $V_{yp} = 0$, implying that V is additively separable) or did not exist (due to independence

of y and p , or fixed p), the risk premium would reduce to the univariate measure.⁵ Otherwise, S differs from the Pratt risk premium in magnitude and possibly in sign.

In the case of a marketed-surplus good, this expression can be simplified somewhat. If the price of output is the only random variable affecting profits and consumption, the above expression reduces to

$$S = -\sigma_{pp} x \left[\frac{1}{2} x \frac{V_{yy}}{V_y} + \frac{V_{yp}}{V_y} \right],$$

because the variance of income, σ_{yy} , is simply the variance of revenues from production, $x^2 \sigma_{pp}$, where σ_{pp} denotes the variance of the output price, and the covariance of income and price, similarly, is $x \sigma_{pp}$. Since the sign S is determined solely by the sign of the term in brackets, this expression suggests that it might be possible to find conditions on utility functions whose owners have a risk premium of a particular sign, regardless of the probability distribution of p . These new conditions are needed since $V_{yy} < 0$, the univariate condition, no longer is sufficient for $S > 0$. This is accomplished in proposition 1, which illustrates the relationships between the sign of S and various parameters of the peasant's preferences, including the marketed surplus (the difference between x and m).

PROPOSITION 1. *Let η be the income elasticity of the household's demand for home-consumption (m) of the farm crop. A necessary condition for a positive risk premium S is*

$$\eta > r \left[1 - \frac{1}{2\rho} \right],$$

where ρ is the ratio of home-consumption to total production (m/x) and r is the Arrow-Pratt measure of relative risk aversion. (A proof of the proposition is available from the authors upon request.)

The expression derived for S using a Taylor-series approximation suggests that, for small risks, this condition is both necessary and sufficient.⁶ Also, if the household consumes less (more) than half of its output, a necessary condition for a positive (negative) risk premium is that the farm-produced good is a normal (infer-

⁴ At first glance, such a risk premium seems to attach a value to an impossible stabilization scheme. The price of the output x could be stabilized independently of the consumption price, however. For instance, the government could operate a consumer subsidy scheme where the price to consumers was uncertain and there was a pre-announced price at which all output would be purchased from producers. A similar outcome could occur if the producer forward contracts all of his output at an unbiased futures price and then decides consumption based on the realization of p . In any event, the concept of the risk premium does not require that such a partial insurance scheme actually be offered.

⁵ Independence is sufficient for that to occur only for small risks. For large risks, independence would not insure equality but would guarantee that S and the univariate risk premium would have the same sign.

⁶ A sufficient condition that holds for large risks as well as small risks is $\eta > r > 0$.

rior) one ($\eta > (<) 0$). If the household consumes exactly half of its output, a necessary condition for a positive risk premium is that the farm-produced good is a normal one ($\eta > 0$). Assuming that $r > 0$, as the proportion of output consumed at home increases, the lower bound on η necessary for $S > 0$ increases as well.

We turn now to the main results of the paper, concerning the level of output for the "marketed surplus" producer. To establish these results, the objective function and risk premium defined above are used.

Optimal Output in the Short-Run

The first-order conditions for the household's maximization problem are

$$(i) \quad E[V_l - V_y w] = 0, \text{ and}$$

$$(ii) \quad E\{V_y[p - c'(x)]\} = 0.$$

Condition (i) requires that the optimal allocation of time equates the expected marginal utility from leisure and the expected marginal utility from the wage payment saved by substituting an additional unit of the owner's labor for hired labor. Condition (ii) states that the expected marginal utility from an additional unit of production vanishes. This condition will be used below to derive qualitative results regarding the level of production. The sufficient conditions for a local maximum are assumed to hold and are given by:

$$a_{11} \equiv E[V_{yy}(w)^2 - 2 \cdot V_{yl}w + V_{ll}] < 0$$

$$a_{22} \equiv E\{V_{yy}[p - c'(x)]^2 - c''(x)V_y\} < 0$$

$$a_{11} \cdot a_{22} - (a_{12})^2 > 0,$$

where

$$a_{12} \equiv E\{V_{yy}[p - c'(x)]w - V_{yl}[p - c'(x)]\}.$$

The second necessary condition can be rewritten as

$$E[V_y p] = E[V_y c'(y)], \text{ or}$$

$$E[V_y(p - \bar{p})] = E\{V_y[c'(x) - \bar{p}]\}.$$

The left-hand side is the covariance between the marginal utility of income and the output price. In Sandmo's model, when the producer is risk averse ($V_{yy} < 0$), this covariance is clearly negative. This is because V_y is decreasing in income and hence in p . This implies that the expected price of output exceeds marginal cost ($\bar{p} > c'(x)$).

This observation leads to the conclusion that, in the classic case, output for risk-averse producers is strictly less than the expected profit-maximizing level.

However, in the case of a peasant producer, p affects V_y not only through the income argument (as captured by V_{yy}) but also through the cross derivative V_{yp} . As a result, $V_{yy} < 0$ is not sufficient to ensure Sandmo's result without more information about the peasant's tastes, production technology, and the probability distribution of prices. Hence, the level of production may exceed the optimal level under certainty. Below we derive plausible conditions under which Sandmo's result is preserved and discuss the consequences of the failure of these conditions for eliciting risk aversion or characterizing behavior. Proposition 2 establishes the conditions under which the level of output is adversely affected by risk.

PROPOSITION 2. *Let the optimal quantities produced under certainty and uncertainty be x^c and x^u , respectively. The relationship between x^c and x^u is given by*

$$x^u \leq x^c \text{ for all risks } \Leftrightarrow \eta \geq r \left(1 - \frac{x^u}{m} \right).$$

Proof. The proof is based on the equivalence of statements (i)–(iv), which holds when conditions (i)–(iii) are required to hold for all price risks:

$$(i) \quad x^u \leq x^c$$

$$(ii) \quad \bar{p} \leq c'(x)$$

$$(iii) \quad \text{Cov}(V_y, p) \leq 0$$

$$(iv) \quad \frac{dV_y}{dp} \leq 0.$$

Using Roy's identity, condition (iv) becomes

$$\begin{aligned} \frac{dV_y}{dp} \leq 0 &\Leftrightarrow \eta \geq r \left[\frac{s_m - \beta}{s_m} \right] \\ &\Leftrightarrow \eta \geq r \left[\frac{m - x^u}{m} \right] \\ &\Leftrightarrow \eta \geq r \left[1 - \frac{x^u}{m} \right], \end{aligned}$$

where s_m denotes the share of the marketed-surplus good in total consumption expenditures and β denotes the share of the risky income in total wealth. \square

The intuition behind the awkward looking expression is clearest using the following relationship involving the consumption parameters, derived by rearranging the first condition on η .

$$x^u \leq x^c \Leftrightarrow r\beta \geq s_m(r - \eta) = s_m r(1 - \mu), \text{ or}$$

$$x^u \leq x^c \Leftrightarrow \beta \geq s_m(1 - \mu),$$

where $\mu = \eta/r$. Besley made use of a "profit" function Φ for the consumer, to represent the expenditure required at any price vector to maintain a particular marginal utility of income. Among other things, this function satisfies

$$\frac{\partial \log \Phi}{\partial \log p} = s_m(1 - \mu),$$

which gives the percentage change in expenditures required to maintain marginal utility following a 1% change in p .

The left-hand side of the above inequality, β , has a similar interpretation; it is the percentage increase in wealth from a 1% increase in the price of output:

$$\frac{dy}{dp} \cdot \frac{p}{y} = x \cdot \frac{p}{y} = \beta.$$

Thus, uncertainty about p has no effect on the "marketed surplus" firm (i.e., $x^u = x^c$) when the change in wealth resulting from a price change equals the change in consumption expenditures needed to maintain a constant marginal utility of income:

$$\beta = s_m(1 - \mu).$$

Effectively, the producer is made risk neutral with respect to price risk because marginal utility of income is constant with respect to changes in p . When the wealth effect dominates, Sandmo's qualitative result is preserved. His result is reversed when the consumption effect dominates.

Proposition 2 also suggests that a crucial factor in the relationship between output levels under certainty and uncertainty is the degree of self-sufficiency of the farm—in other words, whether or not there is a marketed surplus. Empirical evidence regarding this parameter of peasants' behavior is provided by Ahmed and Bernard (table 1, p. 17). They reported that 40% of the farms in Bangladesh are deficit farms—net buyers of rice.⁷ Only 30% of the rice farms in this

country always have a positive marketed surplus.

Returning to the proposition, a sufficient condition for Sandmo's qualitative result to hold for the latter type of farms is that the good produced be a normal good ($\eta > 0$); the lower bound on η given in the proposition will be negative, ensuring a Sandmo-like response for risk. On the other hand, for the other 40% of the farms that are net buyers of rice, a positive income elasticity becomes a necessary condition for Sandmo's result to hold while a negative one is sufficient for a reversal of that result.

If the producer does not consume any of his farm product ($s_m = 0$), the level of output is separable from preferences for goods and, just as in Sandmo's model, risk aversion is sufficient for uncertainty about the price of output to affect production adversely. Alternatively, this last result is obtained if the variable indirect utility function is additively separable in income and the price p for consumption of m . However, this condition implies rather restrictive preferences because it requires that $\eta = r > 0$.

Examination of propositions 1 and 2 illustrates an important difference between the cases of univariate and multivariate risk. The condition for a positive risk premium, in the Sandmo framework, is identical to the one for a level of output that is less than under certainty. However, in the current framework, the condition that ensures a smaller level of output under uncertainty differs from the condition for a positive risk premium. Thus, a producer may prefer a stable income and, at the same time, produce more than under certainty.

Figure 1 illustrates the above results. In each of the four graphs, the relationship between the optimal level of output (x) and the coefficient of variation of price (ψ) is given for three levels of aversion to risk, as measured by the Arrow-Pratt measure of relative risk-aversion ($r = 0, 1/2, 1$). The cost function is $1/2x^2$ and the mean price is assumed, for simplicity, to be 1. The four graphs combined show the effects of η , the income elasticity of demand for the marketed-surplus good, and ρ , the ratio of home consumption m to total output x .

In figure 1a, the optimal level of output is shown to decrease with respect to risk for three levels of r . The Sandmo results hold, in the sense that increases in r or in the uncertainty about the output price (as measured by ψ) reduce the optimal output. However, note that output is affected by increasing risk even when the pro-

⁷ The required purchasing power comes, presumably, from other outputs or from off-farm sources of income.

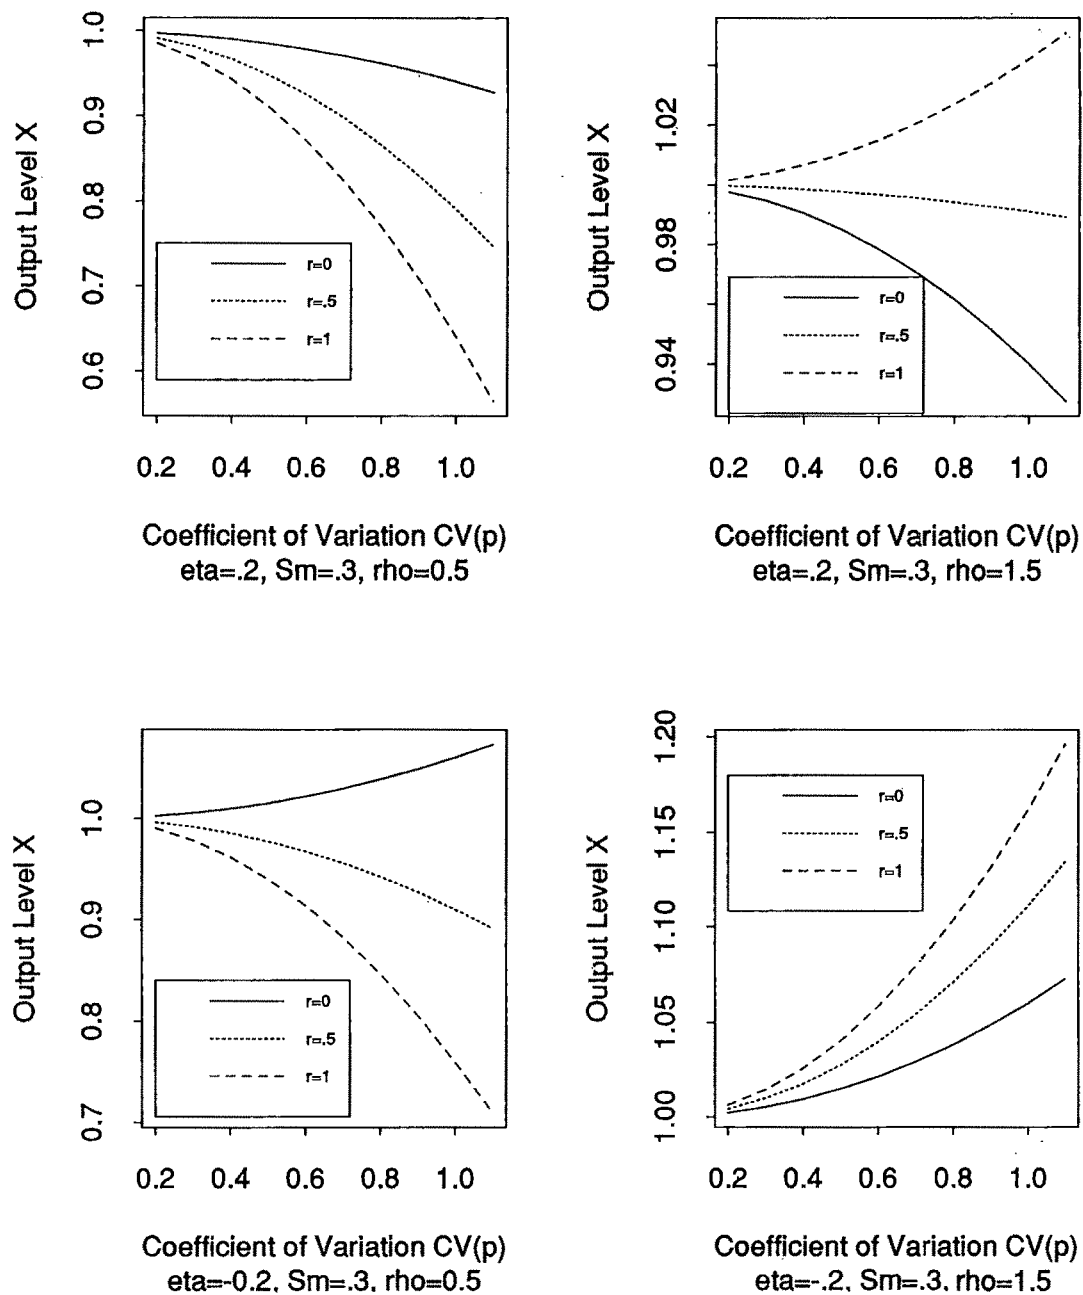

Figure 1. Effects of risk and risk aversion on output levels

lucer is risk neutral. Such a producer is indifferent to the income risk associated with p but not the consumption effect. Returning to the condition

$$\eta > r \cdot \left[1 - \frac{1}{\rho} \right],$$

the risk-neutral producer will produce less than under certainty if $\eta > 0$, more if $\eta < 0$, and will be unaffected only if $\eta = 0$. In figure 1b, everything is the same except the producer is a net buyer of the product; here ρ is 1.5. The risk-neutral and slightly risk-averse producer's behavior is qualitatively the same as

before, while the more risk-averse producer increases output with an increase in risk. Also, note that increases in r are associated with increased output for a given level of risk.

Figure 1c shows that a risk-neutral producer may also increase output as risk increases. In this case, the producers are net sellers, but the good is an inferior good. The Sandmo result concerning increases in r thus holds, but the negative value for η causes the increase in output, as risk increases, to be lessened for risk-averse producers. The risk-neutral or only slightly risk-averse producer actually produces more as risk increases; how risk averse one could be and still exhibit this behavior would vary with the levels of η , s_m , and ρ .

Finally, the combined effects of a negative value for η and being a net buyer are shown in figure 1d. Here, both aspects of the usual responses to risk are reversed. Increases in risk cause all producers to increase output, and the level of output is increasing in r for any level of risk.

Implications for Econometric Studies

Econometric studies of peasants' risk attitudes (e.g., Antle) are usually based on the observed gap between expected revenue and marginal cost. In the traditional model, this gap equals the derivative of the Pratt risk premium with respect to output (e.g., Antle, Flacco and Larson). This last quantity, termed the marginal risk premium, is a function of the observed moments of the probability distribution and the agent's risk attitudes.⁸ This relationship permits the agent's degree of risk aversion to be inferred by a comparison of the above gap to the variance of profits.

However, this relationship is misspecified if the agent's objective function is defined over other random variables as well. The wrong risk premium will have been used. Instead, the derivative of the risk premium S defined earlier is appropriate. For a correct elicitation of aversion to risk in such cases, one needs information about the moments of the joint distribution of the different risks in the objective function and about the agent's attitudes toward the other risks. These may depend, as was shown in the preceding section, on the agent's ordinal preferences.

Suppose that the small risk assumption is valid.

A first-order Taylor approximation of the producer's first-order condition yields

$$\frac{\bar{p} - c'(x)}{\bar{p}} = \psi^2 [r\beta + s_m(\eta - r)],$$

where ψ is the coefficient of variation of the output price. Data on \bar{p} , ψ , production inputs, and output would facilitate the estimation of the coefficient of ψ in the above equation. Previous studies have interpreted the coefficient on ψ^2 or on variance as the Arrow-Pratt measure of risk aversion (e.g., Antle, p. 774). However, in the marketed-surplus case, this coefficient clearly cannot be interpreted as a coefficient of risk aversion because it also includes parameters that describe ordinal preferences for home consumption. Even if it is known that β is around one, so that safe income is negligible compared to the farm income, such an inference is not possible. When $\beta = 1$, one obtains a linear combination of r and η , with the weights determined by the size of s_m ; the larger is s_m , the more the estimate includes the effects of η . And, if the sufficient condition for Sandmo's result holds—that η is larger than r and both are positive—the result is that the estimated degree of risk aversion is too large.

When does this quantity reduce to the Arrow-Pratt measure of risk aversion? Two alternatives exist. First, $s_m = 0$, so the producer does not consume any of his farm product. Second is the case where $\eta = r$, which was discussed in preceding section. As in the traditional model, if these conditions hold, estimation of an individual's attitude toward risk is possible using the observed gap between expected price and marginal cost. However, if $s_m > 0$, so that the peasant consumes a significant portion of the product grown on his farm, and his variable indirect utility function is not additively separable, the traditional estimation procedure yields biased estimates.

In some extremes, the result may even be estimates with the wrong signs, indicating risk-seeking behavior although the agent is, in fact, risk averse. The above expression for the first-order condition reveals that if $s_m > \beta$ and $\eta \leq 0$, the level of output under uncertainty is increasing in the Arrow-Pratt measure of relative risk aversion. Thus, if the producer is a net buyer of the farm product,⁹ and the good is inferior,

⁸ Typically, researchers have assumed small risks, so only the second moment, variance, matters.

⁹ That this might occur seems rather surprising, but the data mentioned earlier from Bangladesh, cited by Ahmed and Bernard, show that it can.

greater risk aversion is associated with a smaller gap between expected price and marginal cost. Hence, in this case if one simply regresses the gap between expected price and marginal cost against variance, the estimated coefficient, mistakenly believed to equal r , will be negative even though the producer is risk averse.

Figure 2 illustrates these findings for some plausible values of consumption parameters. On the vertical axis is the expected value of the estimated coefficient in the simple regression where the dependent variable is the percentage gap between expected price and marginal cost and the explanatory variable is the coefficient of variation of the output price. The horizontal axis gives values of the Arrow-Pratt measure of relative risk aversion.

Ideally, the relationship between these two would be given by a 45-degree line from the origin. The figure illustrates that this is not the case when the estimation procedure is based on a simple univariate Sandmo-type model. Ignoring multivariate risk causes behavior that is partly the result of uncertainty about a consumption price to be ascribed solely to aversion to income risk.

If $\rho = 1$, the Arrow-Pratt coefficient of risk aversion has no effect on the estimate. In fact, the regression coefficient is an unbiased estimate of the product of the income elasticity and the budget share. For deficit farms ($\rho > 1$), one is likely to obtain negative relationships, as the figure shows: increases in the value of r lead to decreases in its estimated value. Only for farms with a positive marketed surplus will greater risk aversion tend to result in larger estimates.

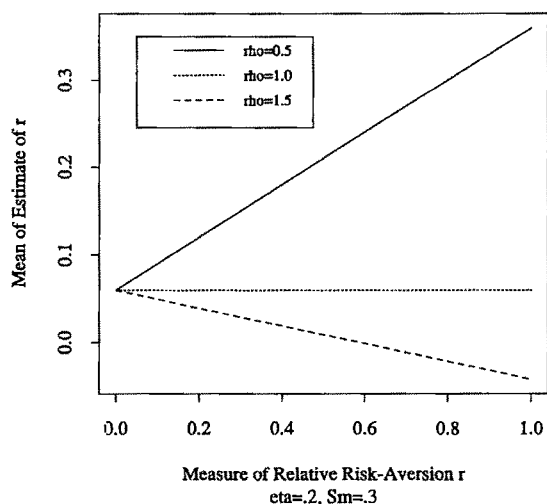

Figure 2. Estimation of risk aversion

Long-Run Entry and Exit Decisions of the Risk-Averse Peasant

The discussion thus far has assumed that the household produces a positive level of output and hence ignores the possibility of quitting farming. However, the effects of price risk may be severe enough to induce farmers to quit the farm and to look for alternative income sources. For example, peasants might choose to migrate from rural areas to urban areas to sell their labor services. This is the topic of the current section, which examines the long-run equilibrium and serves to illustrate how the modified risk premium can lead to different conclusions than the usual risk premium.

Proposition 3 generalizes the results of Sandmo, Paris, and Flacco and Larson, establishing the relationship between the peasant's attitude toward risk and the difference between expected price and average cost which induces entry/exit. Because the cost of production includes the opportunity cost of the peasant's labor endowment (that opportunity cost being the urban wage), the proposition yields the conditions under which it would be optimal to quit farming and migrate to the city.

PROPOSITION 3. *Exit from farming occurs where average cost is smaller (larger) than expected price if and only if the peasant is averse to (seeks) income risk, in the sense that $S > (<) 0$.*

Proof. We prove the result for aversion to income risk; the case of risk seeking can be proved similarly. Let the initial level of wealth be W_0 and profits from farming π . The producer is indifferent between his two alternatives if and only if expected utility is the same whether he produces or not:

$$E[V(l, \pi + W_0, p)] = E[V(l, \bar{\pi} + W_0 - S, p)] \\ = E[V(l, W_0, p)], \text{ or}$$

$$\bar{p} = \frac{C(x)}{x} + \frac{S}{x} = 0. \quad \square$$

Various researchers (cited in Katz and Stark, for instance) have presented surprising evidence that migration has occurred even though "in many cases the expected income in the urban area is not larger than the expected income in the rural area" (Katz and Stark, p. 135). Risk aversion in the Arrow-Pratt sense can explain such migration if income sources in the city are safer. However, urban job markets in developing

countries are often characterized by a high level of uncertainty about employment.

Katz and Stark suggested imperfections in the capital market as a possible explanation. Another alternative is provided by aversion to income risk, as captured by a positive value for our modified risk premium S . Recall that S consists of the Arrow-Pratt premium plus an additional term. This additional term may be positive, providing an additional reason to quit farming. It may turn out, then, that peasants will be willing to bear additional income risks in the urban area—to escape a positive correlation between income and a consumption price—thus reconciling migration with aversion to income risk.

Turning to the industry, in long-run equilibrium each participant in the industry must be indifferent between operating or quitting farming. This requirement implies the following characteristics of the long-run equilibrium, stated as corollary 1, an immediate result of proposition 3.

COROLLARY 1. *If the industry consists of peasants who are averse to income risk, the long-run equilibrium is characterized by positive expected profits.*

The above condition replaces the traditional “zero profits” characterization of the long-run equilibrium of the industry under certainty. Thus, the average risk premium drives a wedge between expected price and average cost. As is true in the case of univariate risk (Flacco and Larson), production under risk, if producers are risk-averse, does not take place where long-run average cost is at a minimum.

Production may also take place even though expected profits are negative. While this could occur in a univariate framework, it would be possible only with risk-preferring producers. Here, it could occur even with risk aversion in the Arrow-Pratt sense ($V_{yy} < 0$), as long as the consumption effect of randomness in p was large enough to yield $S < 0$. To summarize, aversion to income risk, as defined by a positive modified risk premium, is both necessary and sufficient for the peasant to produce only when expected profits are strictly positive, while the Arrow-Pratt measure is neither necessary nor sufficient.¹⁰ An empirical implication of this, once more, is that even if positive expected profits

are observed in the long run, one cannot conclude that producers are risk averse in the sense of Arrow and Pratt. Similarly, negative expected profits (or apparently suboptimal exits from farming) need not imply risk-preferring behavior.

Discussion of Possible Extensions

Uncertainty about prices is indeed one of the important risks with which peasants must contend. For example, Newbery and Stiglitz and Ahmed and Bernard present evidence that in developing countries, the coefficient of variation of the price of a typical agricultural commodity is around 0.5. However, additional risks affecting profits or other arguments of the utility function are typically present.

Uncertainty about the relative prices of other commodities consumed is another risk that may be present in the utility function. It is unlikely that the producer faces output price risk while all other prices in the economy are known or move together (pure inflation), as essentially was assumed in our model. It is straightforward to generalize our results, however. The risk premium S is defined as before, but p now denotes a vector of goods' prices. For small risks, it can be shown that

$$S = -\frac{1}{2} \sigma_{p_x}^2 x^2 \frac{V_{yy}}{V_y} - \sum_{i=1}^N \sigma_{p_x p_i} x \frac{V_{yp_i}}{V_y}.$$

This is a generalization of the risk premium of the second section of the paper, which was defined for the case of uncertainty about the price of output and the price of one consumption good. This expanded risk premium consists of the univariate income-risk premium and a term capturing the individual's aversion to the covariation of income (through the output price p_x) with all other prices p_i ($i = 1, \dots, n$). The latter could be positive or negative.

Both components of S have a derivative with respect to output; as a result, the marginal risk premium, which represents the difference between price and marginal cost, could have a sign opposite to that of the univariate risk premium. However, unlike the special case of the earlier section, where only the price of the marketed surplus good is random, knowing the sign of the marginal risk premium now requires knowledge of the covariances between prices and of preferences (each V_{yp_i} term). Our analysis that considers only the price of the marketed surplus good

¹⁰ The modified risk premium is also useful for interpersonal comparisons. For example, it can be shown that a peasant who is more averse to income risk would require a higher expected price to remain in farming.

is thus a special case of the more general problem in which all prices are random. As long as other goods tend to have small budget shares and the risks in their relative prices have small degrees of correlation with the output price, it might be reasonable to assume that the overall effect on production of these other risks is negligible. Otherwise, at least for small risks, the expression above replaces the risk premium we used. It complicates the interpretation of the conditions for Sandmo's result or for a positive risk premium because information about all goods is required, but it is still S , and not the univariate risk premium, that describes behavior. In fact, the multivariate risk premium S replaces the univariate (Arrow-Pratt) risk premium any time the situation is one of multivariate risks (Karni, Finkelshtain).

Other risks also affect profits. Certainly, peasants are exposed to uncertainty about yields as well as prices. To accommodate this additional uncertainty, the model must be extended in two directions. First, it must be modified to allow the choice variables to be inputs rather than the level of output. Second, the risk premium is more complicated. Assuming small risks and returning to the case that other goods prices are known, the willingness to pay to stabilize income risk, when it consists of both yield risk and output price risk for the marketed surplus good, is given by

$$S = -\frac{1}{2} \sigma_{yy} \frac{V_{yy}}{V_y} - \sigma_{yp} \frac{V_{yp}}{V_y},$$

where σ_{yy} , the variance of revenues, now reflects variation in price and output, as well as their covariance. In addition, the covariance between income and the price of the good, σ_{yp} , is no longer the same as $\sigma_{pp} \cdot x$; hence, this expression cannot be simplified any further. Both the covariance term and the derivative V_{yp} must be signed before the effect of risk can be determined. Since σ_{yp} depends on the level of production, the marginal risk premium is once more affected by the added risk.

This causes some difficulty in establishing results analogous to propositions 1 and 2. These propositions were based on the assumption that only price risk exists. The risk premium S still may be interpreted as before, but because profits now depend on additional risks, the characterization in proposition 1 of preferences that imply $S > 0$ is no longer valid. Moreover, a proposition similar to proposition 2 is hard to derive because, except for extreme cases such

as where profits and the output price are perfectly correlated, it is impossible to find an expression for dV_y/dp_i of condition (iv).

The conditions under which a producer will always behave as a risk averter with respect to output or will always be willing to pay a positive premium to stabilize income are thus much stronger. While more difficult, the problem is not intractable. Either the problem must be attacked for small risks only, with the Taylor approximation of S , or restrictions must be placed on preferences to obtain large-risk characterizations of behavior.

The main conclusions remain valid: the level of output may well be greater than under certainty, and ordinal preferences affect the level of production. In fact, it can be shown that, for any preferences (except the logarithmic utility function), there is always some probability distribution that implies a higher output level under uncertainty. Also, if additional restrictions are imposed on the joint probability distribution of wealth and the price of consumption goods, a broader set of preferences will imply Sandmo's result. For instance, if they are independent (e.g., if the producer receives a certain price for his output but faces yield risk that is independent of the risk in the prices of consumption goods), it is required only that the producer is averse to risk in the Arrow-Pratt sense.

It is important to emphasize that our discussion in the two preceding sections of the paper also remains valid. An empirical analysis that does not explicitly consider the producer's ordinal preferences for goods will yield biased results if interest is in estimating risk attitudes. Also, aversion to a specific income risk, as defined by $S > 0$, would imply positive expected profits in the long run, and a more risk-averse producer will demand a higher expected price to stay in business.

Conclusions

This paper has shown that many of the familiar results from models of output price uncertainty may no longer hold when producers consume a significant share of their own output. In the short run, a peasant producer who is averse to risk may find it optimal to produce either more or less output than the level that maximizes expected profits. The necessary and sufficient conditions for each of these alternatives were derived. The univariate (Arrow-Pratt) measure of aversion to risk is not sufficient to determine

which will occur. However, the alternative risk premium developed in the paper, which measures aversion to risk in income when other random variables affect utility, does provide a characterization of risk aversion and of the level of output.

Implications were drawn for empirical studies that attempt to determine risk attitudes from observed behavior. Estimates or predictions that use univariate models will, in general, be biased for the case of peasants. Finally, in the long run, the average price the peasant producer requires to remain in business may be larger, equal to, or smaller than average cost.

Market Integration, Efficiency of Arbitrage, and Imperfect Competition: Methodology and Application to U.S. Celery

Richard J. Sexton, Catherine L. Kling, and Hoy F. Carman

This paper develops and applies a methodology to test for efficiency of interregional commodity arbitrage. Application of the methodology requires only time-series data on prices for alternative cities, regions, countries, or product forms. Yet, the approach is capable of generating evidence on a number of market parameters including market integration, arbitrage efficiency, the magnitude of marketing margins, product substitutability, and competitiveness of markets. Estimation is based on a switching regression model with three regimes: efficient arbitrage, relative shortage, and relative glut. Results from application of the model to U.S. celery marketing indicated significant departures from efficient arbitrage for both California and Florida celery.

Key words: arbitrage, celery, imperfect competition, law of one price, market integration, price efficiency.

The nature of markets and their role in price determination are central to economics. Geographic markets are particularly relevant to agriculture because agricultural products are typically bulky and/or perishable and areas of production and consumption are separated; hence, transportation is costly. The geographic boundaries of a market are important in the measurement of supply and demand, in price discovery, and in the structure of competition. Despite this importance, Stigler and Sherwin (p. 555) have noted that "the infrequency with which one encounters actual market size determinations outside the antitrust area is surprising and perhaps disquieting." However, a methodology developed recently by Spiller and Huang to define wholesale gasoline markets geographically may contribute importantly to this line of inquiry. This paper extends the Spiller and Huang approach to measure arbitrage efficiency and adapts the methodology to an agricultural markets context.

An application to U.S. fresh celery markets is also provided.

Contemporary studies of economic markets (and definitions of a market) are usually based on the fundamental definitions of Cournot and Marshall. Two regions are in the same economic market for a homogenous good if the prices for that good differ by exactly the interregional transportation cost. Alternative statements of this same arbitrage concept are that (a) the regional markets are integrated (Goodwin and Schroeder), and (b) the law of one price holds between the two regions (Carter and Hamilton; Goodwin, Grennes, and Wohlgenant).

The failure of two or more regions to adhere to the law of one price may be explained by one or more of the following considerations: (a) the regions are not linked by arbitrage, i.e., they represent autarkic markets (Spiller and Huang); (b) there are impediments to efficient arbitrage, such as trade barriers, imperfect information, or risk aversion (Ravallion, Buccola 1983); or (c) there is imperfect competition in one or more of the markets (Stigler and Sherwin, Faminow and Benson). This latter point is relevant because a normative conclusion often drawn from market integration analysis is that observance of the Marshallian arbitrage condition across markets

implies the existence of efficient, competitive arbitrage forces. However, Faminow and Benson have observed recently that this conclusion is justified only for the prototype point-space trading model wherein "effectively, all buyers and sellers [within a region] are located at a single point" (p. 49).

Information on market integration may, therefore, provide specific evidence as to the competitiveness of markets, the effectiveness of arbitrage (Carter and Hamilton), and the efficiency of pricing (Buccola 1983). However, as Faminow and Benson's work demonstrates, it may be difficult to discern the specific cause(s) of observance or failure to observe the law of one price. This point will be developed further in the following discussion.

Previous Approaches

The traditional methodology to study market integration relies on correlations between the prices in pairs of regions (Richardson, Horowitz). For example, a typical regression model to test for short-run market integration might be

$$(1) \quad P_t^i = \beta_0 + \beta_1 P_t^2 + \beta_2 T_t + e_t$$

where P_t^i , $i = 1, 2$ is the price in region i at time t for a homogenous good, T_t is the transactions cost at t required to ship a unit of the good between the two regions, and e_t is a random error term. A test for short-run integration is provided by the joint hypothesis:

$$(2) \quad H_0: \beta_0 = 0, \beta_1 = \beta_2 = 1.0.$$

Because common shifts in supply and demand may induce substantial correlation among the P_t^i even without interregional arbitrage, analysts have considered variations of equation (1) based upon correlations of price differences (Stigler and Sherwin, Carter and Hamilton).

Researchers have also become increasingly concerned with distinctions between short- and long-run market integration. As Ravallion argues: "in many settings it will be implausible that trade adjusts instantaneously to spatial price differences, so one would be reluctant to accept short-run market integration as an equilibrium concept" (p. 103). The model proposed by Ravallion to test for short- versus long-run integration involves correlating price in one region with lagged own prices and contemporaneous and lagged prices in another region. For example,

$$(3) \quad P_t^i = \sum_{i=1}^n \beta_i P_{t-i}^1 + \sum_{j=0}^n \gamma_j P_{t-j}^2$$

The test of short-run integration is the hypothesis $\gamma_0 = 1.0$, $\gamma_j = 0$, $j \neq 0$, and $\beta_i = 0$ for all i , while the corresponding long-run integration condition requires that $\sum_{i=1}^n \beta_i + \sum_{j=0}^n \gamma_j = 1.0$.

The recent contributions of Goodwin and Schroeder and Goodwin, Grennes, and Wohlgenant are in the same spirit. As Goodwin and Schroeder note (p. 174): "Interregional trade takes time to arrange and to complete. Because of delivery lags, trade between regions is conducted based upon *expectations* of future market conditions" (emphasis added). Thus, these authors construct rational expectations models of arbitrage wherein the market integration condition is one of transportation-cost-adjusted equality between current price in the exporting region and expected future price at the delivery time in the importing region.

However, in competitive markets with continuous trade, failure to observe short-run integration of prices implies normative inefficiency in the arbitrage process. Thus, although long-run integration may be regarded as the more realistic equilibrium concept, short-run integration remains a normative benchmark for market evaluation.

Also short-run market integration may be a more realistic equilibrium condition than the preceding authors imply. For example, in the common trade scenario where one region or country is a dominant exporter shipping to many importers, the flow of product from the exporter to the various importers is nearly continuous. Thus, the efficient arbitrage response to a relative price increase for importer A is not necessarily new shipments to A from the exporter but, rather, a rerouting of shipments from other destinations to A. Depending upon the geographic constellation of importing regions/countries, this adjustment process may occur very quickly, making the law of one price a realistic short-run equilibrium condition.

Faminow and Benson's concern is not the methodology of market integration analysis but rather the interpretation of estimation results, which they show hinges critically on the assumed model of spatial competition. Most prior work has been interpreted from the perspective of the standard point-space trading model (Takayama and Judge) common to international or interregional trade analyses. Here, production and consumption regions are geographically

separate and competition is usually considered only in so far as it emanates from multiple sellers (buyers) located at the production (consumption) point.

Benson and Faminow note, however, that the intraregional trading model (e.g., Greenhut, Norman, and Hung) may be more appropriate in arbitrage analysis for some agricultural commodities. This model embodies a spatial distribution of both buyers and sellers along, say, a line or appropriate two-dimensional surface. Competition is then usually from spatially dispersed buyers and/or sellers, although multiple buyers/sellers may be located at a given point.

The key Faminow and Benson conclusion is that estimation results will be interpreted quite differently from a point-space trading model perspective than from the perspective of spatially dispersed buyers and sellers. For example, short-run market integration may imply anti-competitive base-point pricing rather than competitive FOB pricing and efficient Marshallian arbitrage.¹

The main inference from these recent studies is that the arbitrage model must be chosen and interpreted carefully relative to the trade and market structure characteristics of the product under study. Is short-run (contemporaneous) integration a realistic equilibrium condition? Is the point-space trading model an appropriate characterization of the market(s), or is the model with spatially dispersed agents a more accurate description (Faminow and Benson)?

The Spiller and Huang (SH) model is directly relevant to those situations when integration of markets based on contemporaneous prices is a realistic equilibrium condition, although the methodology is extended in this paper to study lagged price effects. In this context the SH approach overcomes a number of lingering methodological problems in arbitrage models: (a) The arbitrary choice of the price in one region as predetermined is avoided. (b) Transaction costs are estimated within the model. (c) Integration is not treated as an "all or nothing" proposition because regions often may be linked by arbitrage in some periods, but not others, depending upon the supply-demand conditions in each region at time t , as well as the magnitude of T_t .

We turn now to describe the basic SH model. With the extensions proposed here, the ap-

proach is capable of addressing a number of market integration questions relevant to agriculture. Our application to fresh celery markets provides an illustration and helps to highlight some of the points raised by Faminow and Benson.

The Basic Model and Extensions

The SH model is constructed in the point-space tradition and applicable to separate regions that have their own supplies and demands for the product in question. The product may be shipped at a cost across regions. Because each region has its own supply and demand, it is possible to identify autarkic prices in each region. SH express the reduced-form equations of autarky prices for two regions at time t as

$$(4) \quad P_t^{1A} = \pi^1 + \epsilon_t^1,$$

$$(5) \quad P_t^{2A} = \pi^2 + \epsilon_t^2,$$

where the π^i are constant means and the ϵ_t^i represent random shocks to the markets. Given free trade across regions, the actual prices, P_t^1, P_t^2 , may differ from the autarky prices. Specifically, if $|P_t^{1A} - P_t^{2A}| < T_t$, no profitable arbitrage opportunities exist and

$$P_t^1 = P_t^{1A}, P_t^2 = P_t^{2A}.$$

However, if the autarky price difference exceeds T_t , SH assume that competitive interregional shipments will take place until the observed prices in each region differ by exactly T_t . In this case the markets are integrated, and

$$P_t^2 - P_t^1 = T_t > 0,$$

where for simplicity region 2 is assumed to be the higher-price region.

Let transactions cost T_t be modeled as a random variable with constant mean, T :

$$(6) \quad T_t = T + v_t, \text{ where } v_t \sim N(0, \sigma_v^2).^2$$

The probability at time t of no arbitrage opportunities between the two regions (i.e., the probability of autarkic markets) is the constant, λ , where

$$\begin{aligned} \lambda &= \text{Prob}\{P_t^{2A} - P_t^{1A} < T + v_t\}, \\ &= \text{Prob}\{(\pi^2 - \pi^1) + (\epsilon_t^2 - \epsilon_t^1) - v_t < T\}. \end{aligned}$$

¹ Base-point pricing is a collusive strategy whereby all sellers offer the same delivered price schedule consisting of price at a given location (the basing point) plus transportation costs from the basing point to other destinations.

² Constant mean transactions costs over time represents a fairly strong assumption of the SH model and implies that empirical applications of the model require relatively short time series and/or periods of relatively stable prices.

It follows that λ is a function of π^1 , π^2 , T , σ_v^2 , and the distribution parameters of the ϵ_i^j . The probability of observing binding arbitrage (market integration) at time t is $1 - \lambda$, where $\lambda \approx 0$ signifies regions that are almost always integrated (in the same Marshallian economic market).

The above model may be expressed as a switching regression system and estimated using maximum likelihood methods. With the SH approach (a) prices are not treated as predetermined variables in the regression model, (b) interregional shipment costs are endogenous and estimated within the model, and (c) the probability that markets are integrated is allowed to vary continuously.

Extensions

Production of many agricultural products is concentrated in only one or a few regions and, hence, does not conform directly to the SH paradigm, wherein regions have indigenous supply sources. For example, U.S. supplies of many fruits and vegetables, depending upon the season, emanate mainly from California and/or Florida. In these cases shipments typically flow from the producing region to various terminal markets across the country, and the concept of regional autarkic markets is of limited relevance.

A question that arises in these agricultural settings is whether product allocation from the producing region to consuming regions takes place efficiently or whether periodic gluts or shortages occur as the result of product misallocations (Buccola 1983, 1985; Berger et al.). Unlike the SH model, episodes of arbitrage failure cannot be attributed to autarkic market equilibria in these cases. Rather, they must be explained by inefficiencies in arbitrage resulting from trade barriers, imperfect information, and risk aversion, or by imperfect competition.

The extension of the SH model developed in this paper is applicable to many agricultural products. These model applications will be characterized by markets logically linked by arbitrage, with tests for the efficiency and/or competitiveness of the arbitrage process. Test results will usually allow the analyst to draw inferences regarding the efficiency of arbitrage with probabilities of gluts and shortages for a given area, the physical dimensions of the market, and product substitutability. For parsimony of presentation, however, the analysis is developed in

the specific context of the application to U.S. celery marketing.

California is the major celery supplier to U.S. markets throughout the year, but the competitive structure varies by season. Shipments data confirm that California supplies some 80% to 85% of the celery to U.S. terminal markets during the summer and fall months (roughly June through November). Nearly 90% of the California crop is shipped via trucks, with most of the remainder shipped by piggyback van. Michigan is the largest of the secondary summer-fall suppliers, with minor supplies also originating in New York, Ohio, Washington, and Canada.

California's share declines, however, during the winter and spring (December through June) when Florida enters as a major producer, accounting for about 25% of total supplies. Although Florida ships celery to all major terminal markets except those on the West Coast, California celery is preferred to the Florida product because of higher quality, more dependable supply, and California shippers' ability in many cases to provide a single source for many fresh vegetables (Berger et al.).

Berger et al. estimate that there are ninety celery growers and about forty large-scale handlers and marketers of celery in California, with none having a large market share. Moreover, there is no centralized mechanism to coordinate shipments in California. This structure contrasts sharply with the Florida scenario, where only about fifteen large grower handlers operate and marketing is regulated by a federal marketing order featuring flow-to-market provisions. Also, nearly all Florida celery growers belong to a centralized marketing organization, the Florida Celery Exchange (Berger et al.). Contracts with growers give the exchange title to the celery and complete control over its marketing (Kilmer).

Market structure analysis indicates strongly that California celery is allocated competitively. Although Faminow and Benson note that spatial markets often tend to be imperfectly competitive and provide incentives for sellers to price discriminate,³ a large number of sellers located at the same production point renders such discrimination infeasible and competitive FOB pricing emerges in equilibrium. (A formal derivation of this result is provided in Greenhut, Norman, and Hung, chap. 8.)

³ Spatial price discrimination occurs when "the difference in delivered prices between any pair of markets is not equal to the difference in transports costs incurred by the firm in supplying those markets" (Greenhut, Norman, and Hung, p. 102).

Because celery marketing is much more coordinated in Florida than California, it is important to ask whether Florida shippers exercise market power and practice price discrimination across consuming markets or whether pervasive competition from California mitigates these opportunities.

Focusing attention first on celery marketing during the summer months, suppose initially that product flows from California are efficient. Then denoting California FOB prices as p_c and wholesale terminal market prices with the corresponding upper case P^i $i = 1, \dots, n$, we have the following equilibrium arbitrage condition for a given time period t :

$$(7) \quad p_{c,t} = P_t^1 - T_t^1 = P_t^2 - T_t^2 \\ = \dots = P_t^n - T_t^n$$

Departures from (7) imply profit opportunities that, given a perfectly competitive supply, should trigger product reallocations from low- to high-price terminals to restore the equality.

However, if product is not allocated efficiently due to risk factors, imperfect information, significant shipment lags, etc. (see generally Buccola 1983), then periodic gluts or shortages may appear in the various terminals and (7) will not hold for all t . For example, Berger et al. speculate that California causes periodic gluts in Eastern markets during summer

$$(8c) \quad P_t^i - p_{c,t} = T^i + v_t^i - u^i \quad \text{with prob } \lambda_2.$$

Here u is a positive random variable so that (8b) defines a regime wherein the wholesale terminal price exceeds the FOB price plus transactions costs—a relative shortage situation in that less product was allocated to the terminal than indicated by the efficient arbitrage condition (8a). Alternatively (8c) corresponds to a market glut, where the terminal price is depressed below the FOB price plus transactions costs because of excess shipments relative to the efficient arbitrage standard.

The equations in (8), thus, define a switching regression model with three regimes: efficient arbitrage, shortage, and glut. To estimate the model, the likelihood function may be formulated as follows:

$$(9) \quad L = \prod_{i=1}^n [\lambda_1 f_t^1 + \lambda_2 f_t^2 + (1 - \lambda_1 - \lambda_2) f_t^3],$$

where f_t^1 , f_t^2 , and f_t^3 are, respectively, the density functions of (8a), (8b), and (8c), and n is the number of observations. To specify these densities, assume that u_t is distributed independently of v_t with a half normal distribution, i.e., an $N(0, \sigma_u^2)$ distribution truncated from below at zero. Then define $Y_t = P_t^i - p_{c,t}$ and express the densities as follows:⁴

$$f_t^1 = \left[\frac{2}{(\sigma_u^2 + \sigma_v^2)^{.5}} \right] \phi \left[\frac{Y_t - T}{(\sigma_u^2 + \sigma_v^2)^{.5}} \right] \left[1 - \Phi \left[\frac{-(Y_t - T)\sigma_u/\sigma_v}{(\sigma_u^2 + \sigma_v^2)^{.5}} \right] \right], \\ f_t^2 = \left[\frac{2}{(\sigma_u^2 + \sigma_v^2)^{.5}} \right] \phi \left[\frac{Y_t - T}{(\sigma_u^2 + \sigma_v^2)^{.5}} \right] \left[1 - \Phi \left[\frac{(Y_t - T)\sigma_u/\sigma_v}{(\sigma_u^2 + \sigma_v^2)^{.5}} \right] \right], \\ f_t^3 = \frac{1}{\sigma_v} \phi \left[\frac{Y_t - T}{\sigma_v} \right],$$

months by making large shipments with “no pre-arranged destination or price” (p. 35).

To extend the SH methodology to test for inefficient product allocation, we define three regimes that exhaust the possible arbitrage conditions between the producing region and any terminal market i :

$$(8a) \quad P_t^i - p_{c,t} = T^i + v_t^i \quad \text{with prob } 1 - \lambda_1 - \lambda_2,$$

$$(8b) \quad P_t^i - p_{c,t} = T^i + v_t^i + u^i \quad \text{with prob } \lambda_1,$$

where $\phi(\)$ denotes the standard normal density function, and $\Phi(\)$ denotes the corresponding cumulative distribution function for the standard normal. The parameters T , λ_1 , λ_2 , σ_v^2 , and σ_u^2 can be estimated by maximizing the log of (9).

During Florida's winter production cycle, the Florida analogue to the California efficient ar-

⁴ The functions f_t^1 and f_t^2 are best understood through their close analogies to frontier functions (Aigner, Lovell, and Schmidt). Specifically, f_t^1 corresponds to a stochastic frontier equation with a positive error (e.g., a cost function), while f_t^2 corresponds to a stochastic frontier equation with a negative error (e.g., a production function).

bitrage condition, (7), can be formulated and also tested via (9), but these results must be interpreted in a manner consistent with the spatial market structure for Florida celery (Faminow and Benson). Spatial price discrimination is a concern given Florida's marketing order, Celery Exchange, and insulation from nearby spatial competitors. Although Taylor and Kilmer concluded that "the weight of empirical evidence . . . suggests that the Florida celery industry has not enhanced price above [the competitive level]" (p. 41), this conclusion was derived from an aggregate conjectural variations model of oligopoly which may fail to capture spatial market power in specific consuming regions.

Thus, to explore this issue further using an arbitrage model framework, note that a price discrimination equilibrium for Florida would be

$$(10) \quad MR_{F,t}^1 - T_{F,t}^1 = MR_{F,t}^2 - T_{F,t}^2 \\ = \dots = MR_{F,t}^n - T_{F,t}^n \leq p_{F,t},$$

where the $MR_{F,t}^i$ denote marginal revenue from Florida celery sales to the various terminal markets i at time t , and $T_{F,t}^i$ are the corresponding per unit transactions costs. The Florida grower price, $p_{F,t}$, represents a blend price based on revenues from the various terminal markets. Marginal revenue in each terminal market is derived, in turn, in the usual fashion from the residual demand facing Florida shippers in that market.

Florida's residual demand is essentially the market celery demand less the competing California supply at each price.⁵ If Florida has no market power, residual demand for its celery is perfectly elastic, $MR_{F,t}^i = P_{F,t}^i$, for all i , and (10) collapses to the competitive equilibrium condition, (7). Two factors suggest, however, that Florida may face relatively inelastic residual demands in those consuming regions nearest to it: (a) Florida has a decided transportation cost advantage over California in these markets and, hence, is less vulnerable to offsetting California shipments, (b) for most functional forms, demand becomes more elastic as a function of distance from the producing to consuming region (Greenhut, Norman, and Hung). In these cases, price discrimination will favor more distance markets in that delivered price to these markets

will not reflect the full incremental transport costs (Greenhut, Norman, and Hung).

To incorporate spatial price discrimination into an SH-type arbitrage model, define M_t^i as an incremental mark-up to the price, P_t^i , at terminal market i in addition to the transactions costs, T_t^i . It follows that $M_t^i > 0$ implies a price mark up over the FOB price and $M_t^i < 0$ implies freight absorption. The equation for delivered Florida price to any terminal market i is thus:

$$(11) \quad P_{F,t}^i = p_{F,t} + T_{F,t}^i + M_t^i.$$

The modified SH model summarized in (8), and (9) cannot formally distinguish the two components of the $P_{F,t}^i - p_{F,t}$ price difference in (11). That is, the coefficient, $T_{F,t}^i$ from maximizing the log of (9) will include both $T_{F,t}^i$ [see eq. (6)] and a sample average for M_t^i . However, if reasonable inferences about the relative magnitudes of the $T_{F,t}^i$ can be made across the various spatial markets, perhaps inferences about spatial price discrimination can be generated from an SH arbitrage model.

Price Premia

A final extension of the SH model with a direct application to celery marketing concerns tests of the product range.⁶ Although agricultural products often are considered homogenous, subtle, but possibly important, product differentiation may exist among nominally similar products. Examples are similar products grown in different regions, different varieties of a particular crop, or meat products with variable characteristics, such as the degree of marbling.

Two products or varieties of a product belong in the same product market if they are close substitutes (Stigler and Sherwin). The most general approach to measurement of substitutability is estimation of cross elasticities of demand, but data deficiencies and econometric problems may render this method impractical (Baker and Bresnahan), especially for products that are close substitutes.⁷ Yet, specific evidence on the substitutability of products believed a priori to be close substitutes will be important when precise product and market definitions are at issue. (For

⁵ This definition of residual demand is technically correct only for the case where Florida and California celery are perfect substitutes. As noted, some evidence, including our own empirical results, suggests that buyers view Florida and California celery as somewhat differentiated products. Baker and Bresnahan derive residual demand functions for the differentiated products case.

⁶ Stigler and Sherwin have also observed that tests of geographic market definition may also be applied directly to questions of product substitution.

⁷ For example, the closer the substitute relationship between two products, the more colinear their prices will be, making it impractical to include both prices as explanatory variables in demand function estimation.

example, see Hayes, Wahl, and Williams for an attempt to test perfect substitutability in an AIDS framework.)

The SH methodology may also be extended to address a hypothesis that two goods are perfect substitutes (in the same product market). The key point is that a stable relationship must exist between the prices of two perfect substitutes. Specifically, we define perfect substitutability as the existence of a stable premium (possibly zero) separating the prices of two products in our application California and Florida celery. That is,

$$(12) \quad P_{C,t}^i - P_{F,t}^i = \alpha^i + \mu_t^i, \quad i = 1, \dots, n,$$

where $\alpha^i \geq 0$ represents the price premium, and $\mu_t^i \sim N(0, (\sigma_{\mu}^i)^2)$. If California and Florida celery are perfect substitutes, then during all periods when both regions ship to a consuming area, arbitrage forces will ensure that the two prices diverge by the premium, α^i .⁸ However, if the two products are not perfect substitutes, then their price difference may systematically range above or below α^i in response to variations in each product's individual supply-demand factors.

The three regimes of our model of geographic arbitrage efficiency correspond exactly to the model to test for stable price premia (perfect substitutability). That is, we can define three regimes to exhaust the arbitrage possibilities across alternative product forms:

$$(13a) \quad P_{C,t}^i - P_{F,t}^i = \alpha^i + \mu_t^i \quad \text{with prob. } 1 - \lambda_1 - \lambda_2$$

$$(13b) \quad P_{C,t}^i - P_{F,t}^i = \alpha^i + \mu_t^i + u^i \quad \text{with prob. } \lambda_1$$

$$(13c) \quad P_{C,t}^i - P_{F,t}^i = \alpha^i + \mu_t^i - u^i \quad \text{with prob. } \lambda_2,$$

where all variables are defined as in (8). The hypothesis $\lambda_1 = \lambda_2 = 0$ tests whether the products are perfect substitutes, and, qualitatively speaking, the magnitude of $\hat{\lambda}_1 + \hat{\lambda}_2$ is inversely related to the strength of the substitute relationship. Conditional upon rejecting $\lambda_1 = \lambda_2 = 0$, differences in $\hat{\lambda}_1$ and $\hat{\lambda}_2$ can be analyzed to determine possible asymmetries in the substitute relationship.

⁸ For example, if $P_{C,t}^i - P_{F,t}^i > \alpha^i$, then buyers will bid up the price of Florida celery relative to California celery to restore the equality in (12).

Estimation

The switching regression models were estimated using weekly price data for U.S. celery for the four-year period, January 1985 through December 1988. Shipping point and terminal market prices were obtained for both California and Florida celery from various USDA Federal-State Market News Service reports. All prices were in terms of dollars per crate.⁹ California's production is year around, but the producing area shifts seasonally. Thus, Central Coast prices were used during the summer and fall, and South Coast prices were used in the winter and spring. The Florida analysis was based on data from Florida's December through May production period.

Two criteria were used in selecting terminal markets for inclusion in the study: (a) significance of the terminal as a receiver of celery, and (b) location of the terminal. The five largest U.S. terminal markets, Boston, Chicago, Los Angeles, New York, and San Francisco, were included under the first criterion, and Atlanta was chosen under the second.¹⁰ However, Florida does not ship celery to the West Coast, so the analysis for Florida shipments was limited to Chicago, Boston, New York, and Atlanta.

California Celery

The maximum likelihood estimation was conducted using the DFP routine in the GQOPT package. Results from estimation of (9) for California-origin celery are summarized in table 1. Most of the estimated coefficients are statistically significant. The probability, $1 - \hat{\lambda}_1 - \hat{\lambda}_2$, of efficient arbitrage is high, not surprisingly, in Los Angeles (0.76) and San Francisco (0.83), those cities nearest the production regions. However, in all cases the $\hat{\lambda}_i$ are either individually or jointly significant causing a rejection of the hypothesis that arbitrage is efficient or that the law of one price holds for all t .¹¹

The less efficient arbitrage in the eastern markets is consistent with prevailing views on price

⁹ The standard celery crate weighs 60 pounds. The number of stalks per crate varies with the size of the celery. Our prices were usually based on 2.5 dozen stalks per crate. Market News prices are often reported in ranges. In these cases we chose the lower bound of the price range for analysis. The rationale for this choice is provided by SH (p. 137).

¹⁰ Industry experts suggested that about 60% of fresh celery is marketed through the terminals, with the rest contracted directly to major retailers.

¹¹ For Atlanta and Boston joint significance of the λ_i was established based on the usual likelihood ratio tests.

Table 1. Parameter Estimates for California Celery Arbitrage

	Los Angeles	San Francisco	Chicago	Boston	New York	Atlanta
T	2.35 (28.28) ^a	3.83 (32.66)	5.45 (1.86)	4.84 (5.82)	4.53 (11.02)	6.31 (23.13)
σ_v^2	0.62 (5.28)	1.28 (5.39)	0.33 (1.68)	0.87 (2.14)	1.05 (3.24)	0.94 (1.74)
σ_u^2	3.94 (3.52)	7.97 (2.29)	2.23 (5.61)	2.65 (2.42)	3.53 (4.46)	3.20 (1.20)
λ_1	0.15 (2.27)	0.12 (1.80)	0.55 (3.69)	0.78 (1.69)	0.61 (2.46)	0.00 (0.00)
λ_2	0.09 (16.12)	0.05 (1.27)	0.26 (2.60)	0.04 (0.63)	0.03 (0.95)	0.18 (1.31)
$1 - \lambda_1 - \lambda_2$	0.76	0.83	0.19	0.28	0.36	0.82
Log likelihood	-323.44	-379.47	-367.42	-373.22	-391.90	-193.15
Observations	209	209	209	209	209	122
T as % of mean price	28	38	46	41	40	52

^a t -statistics are in parentheses.

ing efficiency (Buccola 1983, 1985). For example, the risk in making unconsigned shipments likely increases with shipment distance due to time lags, possible loss in quality, etc. Quantity and quality of information on market conditions may also decline as a function of distance between shipping point and receiving point. The Atlanta result, $1 - \hat{\lambda}_1 - \hat{\lambda}_2 = 0.82$, differs from the results for the other eastern terminal markets but is explainable by Atlanta's close proximity to Florida production. That is, through the substitute relationship, a glut or shortage of California celery can be corrected by an adjustment in either the California supply or the competing supply from nearby Florida.

Particularly relevant are the comparative magnitudes of the $\hat{\lambda}_i$. In each of the markets studied, except Atlanta, $\hat{\lambda}_1 > \hat{\lambda}_2$. Thus, each of the five major terminals was more often characterized by relative undersupply than oversupply of celery, and no support is found for the Berger et al. conjecture that California causes market gluts in the major eastern markets.

The estimates of mean arbitrage costs in table 1 are all highly significant. With one exception, Chicago, \hat{T}_C^i is increasing in distance from the producing area. The Chicago result may signal relative inefficiencies or imperfect competition in the Chicago-area transportation and marketing network. Also interesting is the significant portion of wholesale California celery prices that is due to shipment costs. This figure ranges from 28% in Los Angeles to 52% in Atlanta, based on mean 1985–88 wholesale prices.

Transportation costs typically account for a major portion of total transactions costs. Because of the assumption of constant mean trans-

actions costs in the model (see footnote 2), possible trends in transportation costs over the period of analysis are of concern. Monthly shipping-point-to-terminal-market truck transportation costs per crate of celery for the 1985–88 period of analysis were obtained from the U.S. Department of Agriculture, Agricultural Marketing Service (USDA AMS), but observations were available for only Atlanta, Chicago, and New York. These data were tested for trends in transportation costs during the period; no statistically significant time trend was detected in these per crate charges. This result supports the assumption that mean transactions costs were constant over this four-year period.¹²

As noted, celery marketing exhibits a seasonal pattern coinciding with Florida's winter-spring production cycle versus summer-fall marketing when California competes with a number of small northern suppliers. Also, truck shipment rates often exhibit a seasonal pattern, with higher rates during summertime peak demand periods. For these reasons the arbitrage model defined in (9) was estimated separately for the December–May and June–November periods. The results are contained in table 2.¹³

No seasonal pattern in the probability of efficient arbitrage is evident in the Los Angeles and San Francisco markets. This result is not

¹² A second analysis involved subtraction of transportation costs from the terminal market price and estimation of the switching regression model for Chicago and New York. Except for the anticipated differences in the magnitude of T , the probabilities of binding arbitrage were essentially unchanged: 0.15 in Chicago and 0.39 in New York versus 0.19 and 0.36, respectively, in table 1.

¹³ Seasonal models were not run for Atlanta because of limited observations. No California celery price was recorded in Atlanta for many weeks because of insufficient shipments.

surprising because these markets are served exclusively by California supplies and, hence, are relatively insulated from changes in the seasonal production pattern. In contrast, a seasonal pattern does emerge in the major midwestern and eastern terminals. In all three cases the estimated probability of efficient arbitrage is greater in the winter than summer and in all cases λ_1 (λ_2) is higher in the summer (winter).¹⁴

These results indicate that it is more difficult for California shippers to engage in efficient arbitrage in the summer-fall months than in the winter and spring. This outcome may well be caused by unpredictable patterns of supply by the small, northern celery suppliers during these months. Efficient arbitrage during winter-spring months is likely simplified by the presence of a single main competitor, Florida, with a coordinated marketing mechanism. In particular, Florida supplies likely are easier to predict and monitor than supplies from the small northern producers, and, as noted, through the substitute relationship, Florida shipments may be quite effective in eliminating gluts or shortages for California celery.

Also interesting to note is that the estimated transactions costs, \hat{T}_C^i , are not consistently higher in the summer and fall despite generally higher truck shipment charges during these months. In fact, in three of the five cases the estimated winter-spring margin was higher, indicating that other components of the margin rise in the winter and spring to offset lower truck rates.

Florida Celery

The results from estimation of the arbitrage model for Florida celery in table 3 must be interpreted cautiously because of the market power considerations discussed above. The probabilities $1 - \hat{\lambda}_1 - \hat{\lambda}_2$ are very similar for all of the Florida markets analyzed, ranging from 0.35 to 0.44. However, it is difficult to provide a firm interpretation of this result. If Florida acted as a competitor in these markets and engaged in FOB pricing, the relatively low values for $1 - \hat{\lambda}_1 - \hat{\lambda}_2$ would indicate a failure on Florida's part to

¹⁴ Likelihood ratio tests were used to test the hypothesis of no seasonal structural change. The values of the test statistic were San Francisco: 3.54, Chicago: 6.82, and Boston: 19.96. The pooled model in table 1 imposes 5 restrictions and $\chi^2_{0.05} = 11.1$. Thus, we reject formally the hypothesis of no seasonal structural change for Boston but not for Chicago or San Francisco. (Similar tests were not performed for Los Angeles and New York because in each case the nonnegativity constraint $\lambda_i \geq 0$ was binding for λ_2 in the summer-fall model.)

Table 3. Parameter Estimates for Florida Celery Arbitrage

engage in efficient arbitrage despite its coordinated marketing mechanism. However, the result could also reflect dynamics in the price discrimination equilibrium (10). The price mark-up term, M^i , in equation (11) may change from period to period in response to variations in Florida's residual demand elasticity caused by changes in competing supplies.

Florida is a minor supplier in the Chicago celery market, with an average 2.4% share over 1985–88. The T^i for Chicago in table 3 is comparatively high, as was true for California shipments. Florida is a more significant player in the Boston and New York markets with 26.8% and 17.8%, respectively, of total fresh market sales during the 1985–1988 period of analysis. The T^i for these geographically proximate terminals are similar, \$2.33 and \$1.93 for Boston and New York, respectively.

The most interesting facet of the Florida analysis is comparison of the Boston, New York, and Atlanta markets. Florida is the dominant seller in Atlanta during the winter. In fact, during some weeks, few, if any, California shipments occur. Although Boston (New York) is roughly 850 (650) miles farther from the Florida producing regions than Atlanta, our estimates of the T_F^i indicate that the margin per crate was actually \$0.43 less for Boston and \$0.83 less for New York than Atlanta. This result is evidence that Florida is employing a discriminating spatial pricing system of the type described previously. Per crate truck shipment rates for celery gathered by the USDA AMS further document this result. These rates were not available for Boston, but the average over 1985–88 was \$2.54 for New York and \$1.06 for Atlanta. Truck shipment rates represent only a portion of the

transactions costs involved in marketing celery. They clearly suggest, however, a significant markup above competitive FOB prices in Atlanta and a healthy amount of freight absorption in New York, just as the relevant spatial theory (Greenhut, Norman, and Hung; Faminow and Benson) predicts.

Some Dynamics

Because of the concerns about short- versus long-run equilibrium in arbitrage (Ravallion, Goodwin and Schroeder, Goodwin, Grennes, and Wohlgenant), the extended SH arbitrage model for California celery was reestimated for alternative formulations of the arbitrage condition. Whereas the prototype model in (8) assumes that integration between contemporaneous FOB and terminal prices is the relevant equilibrium concept, alternative formulations may be based on lagged price relationships as suggested by Goodwin, Grennes, and Wohleganant.

A price determination process whereby the law of one price may emerge for lagged prices can be motivated as follows: California FOB prices are based on current supply and demand conditions facing shippers. This demand, in turn, is derived from retailers' demands and demands in the terminals markets. No single terminal is apt to be large enough to have a significant influence on the FOB prices. Weekly terminal wholesale prices are based on supply-demand conditions in that market. When, for example, $P_t^i > p_{C,t} + T_t^i$, a profit opportunity for shipments to market i is signalled if shipments occur instantaneously. The same market signal is received when shipments occur only with a time

lag if the contemporaneous price is used as the expected future price, i.e., $E_t[P_{t+1}^i] = P_t^i$.¹⁵

If shipments arrive with, say, a j period lag, the relevant integration condition is between $p_{C,t}$ and P_{t+j}^i . Given the speed of transcontinental truck shipments, the longest feasible lag to consider for celery is one week. To test for lagged price integration, the extended SH arbitrage model was reformulated and estimated by alternatively substituting P_{t+1}^i or $(P_t^i + P_{t+1}^i)/2$ for P_t^i everywhere in (8) and redefining Y_t accordingly in specifying the f_t^i .

Results from estimating these models are provided in table 4 where the models based on P_{t+1}^i and $(P_t^i + P_{t+1}^i)/2$ are denoted as the "lagged" model and "average" model, respectively. Results for the prototype model (8) (table 1) based on contemporaneous prices are included for comparison.¹⁶

The table shows that the probability, $1 - \lambda_1 - \lambda_2$, of observing binding arbitrage in the Los Angeles and San Francisco terminals is similar across the three arbitrage conditions. This result is again consistent with their proximity to the production region. However, the probability of observing the lagged arbitrage regime, $P_{t+1}^i - p_{C,t} = T_t^i + v_t^i$, is greater in each of the eastern and midwestern markets than is the probability of observing contemporaneous arbitrage, $P_t^i - p_{C,t} = T_t^i + v_t^i$. This result provides some support for the hypothesis of lagged adjustment to market conditions as distance from the producing to the consuming region increases. The probability of observing the "average" relationship, $(P_t^i + P_{t+1}^i)/2 - p_{C,t} = T_t^i + v_t^i$, is even greater in these three terminals.

Further information on the dynamics of price response in this market is obtained by comparing the log likelihood values in the table. For this purpose the contemporaneous integration model was reestimated to reflect observations lost in the lagging process ($n = 207$ vs. $n = 209$). This likelihood value is denoted as the "comparison likelihood" in the table.¹⁷ The log likelihood is greatest for the contemporaneous integration model for both Los Angeles and San Francisco, but the model using the average of P_t^i and P_{t+1}^i generates the greatest log likelihood

^a *t*-statistics are in parentheses.

in the midwestern and eastern terminals. These results thus provide support for an arbitrage model based on contemporaneous prices in terminals near the producing area and on a short lagged price relationship elsewhere.

Price Premia Results

The final aspect of the empirical analysis involved direct comparison of California and Florida celery prices in the various terminal markets. The results from estimation of the price premium model (13) are provided in table 5. The estimated price premia, $\hat{\alpha}^i$, are similar for the Atlanta, Boston, and New York markets, ranging from \$2.31 to \$2.90 per crate. The $\hat{\alpha}^i$ is much lower, \$0.76, in Chicago, but its *t*-statistic indicates that this coefficient was estimated imprecisely.

The most interesting facet of this analysis is that the estimated probability, $1 - \hat{\lambda}_1 - \hat{\lambda}_2$, of observing a stable price premium is nearly zero in each of the markets. It bears repeating that if buyers viewed California and Florida celery as perfect substitutes subject to a price premium, then buyer arbitrage should ensure that prices diverge by exactly the premium whenever product from both states is available. Thus, the conclusion is that buyers do not view California and Florida celery as perfect substitutes, and their price difference is free to vary somewhat above or below the estimated premium in response to market conditions.

Conclusions

This paper has extended Spiller and Huang's methodology to test market integration and ap-

plied it in an agricultural markets setting. One extension was to regions known to be linked in trade, specifically the common situation in agriculture of one or a few localized production areas. When perfect competition in product allocation and FOB pricing can be safely assumed, this extended model allows for tests of three regimes: (a) efficient arbitrage (i.e., the law of one price), (b) relative shortage, and (c) relative glut. A second extension enabled limited testing of products' substitutability in demand.

Results from application of the extended models to celery marketing indicated that California shipments to out-of-state markets in nearly all cases departed with significant probability from the efficient arbitrage condition. However, no evidence was found to support the hypothesized eastern market glut scenario. The probability of binding arbitrage did increase substantially with the introduction of lags associated with physical transfer of the product from California to distant markets. A seasonal pattern in California marketing efficiency was detected in midwestern and eastern terminals, with efficient arbitrage apparently made easier in winter-spring months by the presence of a single main competitor, Florida, versus many small northern rivals in the summer-fall months.

Interpretation of results from analysis of Florida celery was difficult because of concerns that Florida may practice spatial price discrimination. Comparison of results for the various terminals tended to support the position that Florida charges prices well above the FOB level in the nearby Atlanta market and absorbs some portion of freight charges in New York. The Florida results highlight that the failure to observe binding arbitrage across pairs of markets

may be due to autarkic markets, inefficient arbitrage, or imperfect competition. Unless it is possible to rule out some of these considerations, it will be very difficult to offer a single explanation for a failure to observe the law of one price.

The methodology illustrated in this paper is parsimonious in its data requirements, needing only time-series price data for alternative cities, regions, countries, or product forms. Yet, by exploiting the flexibility of the approach and the available economic theory concerning the underlying market structure, evidence may be generated on a number of market parameters including market integration, arbitrage efficiency, magnitude of marketing margins, product substitutability, and competitiveness of markets.

In many cases more detailed information will be needed than can be provided by an approach that relies solely on price data. Of course, the downside to detailed structural market models is their demands on data, which often compel undesirable levels of aggregation and use of dubious proxies for otherwise unmeasurable variables.

An Empirical Analysis of Economic Performance Under the Marketing Order for Raisins

Ben C. French and Carole Frank Nuckton

This study utilizes a dynamic econometric model of the California raisin industry to compare predictions of prices, production, profits, and related measures under the volume control program with predictions under several no-control scenarios. The outcomes are evaluated in relation to performance criteria proposed by a USDA study team. The twenty-two-year comparisons suggest that the public interest may have been well served by the raisin volume control program, or at worst there was no significant welfare loss.

Key words: econometric model, marketing order, raisins.

Marketing order programs that control the quantity of a product marketed have been authorized for a number of fruit and vegetable commodities as a means of mitigating the negative effects of variable supply and demand on returns to producers. Although there have been some theoretical analyses of the price stabilization aspects of such controls and a few empirical studies, views on applicable performance criteria differ and empirical measurement of social welfare indicators has proved quite difficult (Heifner et al.; Armbruster and Jesse; U.S. GAO; Jesse; French 1982, 1988).

The California raisin industry has had a federally authorized volume control program in effect since 1949. Under this program, the industry is permitted to set aside a portion of the crop in a reserve pool. Raisins in the reserve pool may be returned to commercial sales when market conditions are favorable or disposed of in noncompetitive outlets such as government purchases for school lunches, sales for alcohol manufacture and cattle feed, and donations to charity. Some reserve pool raisins have been exported at prices competitive with world prices but below those on the domestic market. Significant quantities of raisins have been allocated

to reserve pools in all years except when supply was low relative to demand.

The objective of this study is to provide evidence as to possible differences in the behavior of prices, profits, production, and related measures of raisin industry performance in the absence of the volume control program. If the volume control provisions of the marketing order were terminated, grower and consumer prices would be expected to be more variable over time and lower in the short run. Some of the burden of inventories likely would transfer to packers. However, with delayed production response feeding back through plantings and removals, the pattern of outcomes over a period of years is not obvious, hence the need for dynamic empirical analysis. While the findings of the study are specific to the raisin marketing order, the modeling approach may be of general interest, and the conclusions may be relevant to the evaluation of similar types of controls for other commodities.

The study procedure is to utilize an econometric model of the raisin industry system to generate and compare historical predictions of prices, outputs, and returns under the control program with predictions of the model modified to reflect likely conditions without volume controls in effect.¹ The approach is a modification

Giannini Foundation Research Paper No. 956.

The authors are appreciative of helpful comments by Gordon A. King and two anonymous *Journal* reviewers.

¹ The historical approach has an advantage over a forward analysis in that random elements such as yields and estimated stochastic disturbances are known. In a forward analysis, yield fluctuations and other disturbances would have to be generated from the variance-covariance structure of the model by repeated runs.

and extension of previous studies of the effects of eliminating marketing order controls affecting annual volumes of fresh lemons (French and Bressler; Kinney et al.), fresh oranges (Thor and Jesse), and cling peaches (Minami, French, and King). A problem encountered in all of these studies was that because the control provisions were in effect throughout the period of available data, possible differences in equation parameters without the marketing order could not be determined (the well-known Lucas critique). Although the problem was recognized, none of the studies attempted to overcome it, and Kinney et al. made only qualitative evaluations.

A similar problem was encountered in studying the raisin industry's volume control program. The method of dealing with the Lucas criticism was to specify several alternative scenarios which involve plausible changes in equation parameters without the reserve pool provision of the raisin marketing order. For example, a study by French and King (FK 1988) of the effects on planting response of terminating the cling peach volume program in 1972 provides a basis for specifying possible changes in the raisin grape planting response.

In comparing economic performance under the volume control program with performance under the no-control scenarios, all exogenous variables and equation parameters remain the same except for those associated with elimination of volume control. To take account of the random fluctuations in supply and demand which motivated the establishment of the reserve pool program, the estimated disturbances of the stochastic equations and actual yield variations are retained as exogenous variables in the various simulation runs.

Because of difficulties in developing meaningful empirical measures of conventional social welfare indicators, the findings are evaluated in relation to six of seven performance criteria proposed by an independent marketing order study team appointed by the U.S. Department of Agriculture (Polopolus et al.). To meet public interest requirements, the study team proposed that a volume control program should not (a) permit farmers to earn persistent above normal profits, (b) increase price variability and uncertainty, (c) impose disproportionate burdens on particular classes of growers or handlers, (d) contribute to chronic surpluses, (e) result in a waste of resources, (f) reduce net revenues to producers, and (g) result in consumer prices persistently higher than justified by costs including a normal profit. Results of our analysis allow evaluation

of the raisin marketing order volume control provision under (a), (b), and (d)–(g) of these criteria.

The Historical Model

Most raisin-grape production is from Thompson seedless grapes and most of the raisin crop is sun dried and is referred to as natural Thompson seedless raisins (NTS). The econometric model of the NTS industry is a slightly revised version of one by Nuckton, French, and King (NFK).² The model groups the economic activities of the industry into four blocks: (1) growers' raisin-grape vine planting and removal decisions and the resulting bearing acreage and raisin-grape production; (2) growers' allocation of raisin-grape production between drying and crushing for wine; (3) the Raisin Administrative Committee's (RAC) decision rules allocating NTS production between free and reserve tonnage and the determination of the outcome of bargaining between independent packers (not associated with the large grower cooperative) and the growers' Raisin Bargaining Association (RBA) for the field price for free raisin tonnage; and (4) domestic and foreign demand functions, packer pricing and inventory decisions, and the RAC's establishment of an export price for reserve pool quantities. The model is simultaneous within blocks 2, 3, and 4; but, since block solutions are determined sequentially within a crop year, it is recursive among blocks.

Model equations were estimated with data from 1963–83. Out-of-sample projections for 1984 and 1985, reported in NFK, were generally within 95% confidence intervals except for predictions of domestic bulk raisin sales (*QB*) and sales to the United Kingdom and Scandinavia, which were underpredicted. The deviations between actual and predicted values were entered exogenously in the simulations so any structural change that may have occurred in 1985 and 1985 would have little effect on the comparative simulations. A brief explanation of the model specifications, estimation procedures, and empirical results follows.

² The main revisions are in the raisin-grape planting and removal equations where an improved measure of grower returns is used and in the reported beginning stock equation where a revised measure of total product movement is used. Also, some typographical errors in table 3 of NFK (not contained in their simulations) were corrected. The NFK simulations explored the effects of the export incentive program and changes in exchange rates, tariffs, production costs, and population. They did not consider the effects of terminating the volume control program.

Block 1. Production of Raisin-Type Grapes

Annual production of raisin-type grapes is determined by bearing acres and yield, with yield treated as an exogenous variable. Bearing acres in t are determined by the identity, $BA_t = BA_{t-1} + PL_{t-3} - R_{t-1}$ where BA is bearing acres, PL is plantings, and R is acres removed.³

The model for estimating planting and removal functions was adapted from French, King, and Minami and FK 1988. Plantings are a function of existing acreage, less any removals, and grower projections of net returns over the expected life of the vines. Expected long-run returns are modeled as a function of past prices less unit costs. Young acreage, a significant factor affecting future industry supply expectations for peaches, was not significant for raisins because the productive life of grape vines far exceeds that of peach trees. Measures of variability of past profits were not significant predictors in the plantings equations for either raisin grapes or peaches.

Acreage removed from production each year is determined mainly by declining productivity associated with biological factors but is also affected by growers' expected returns. If growers expect favorable returns the next year, they may retain some marginal vineyards another year, decreasing removals, and vice versa. Profit expectations for year t are related to recent profit experience; however, the expectations horizon is shorter than for planting decisions.

Ordinary least square estimates of the planting and removal functions are (values in parenthesis are t -statistics; d is the Durbin-Watson statistic):

plantings ($R^2 = .83$, $d = 1.78$)

$$(1) \quad PL_t / (TA - R)_{t-1} = .01211 + .000979 \text{ NGD3}_{t-1}, \quad (7.59) \quad (9.55)$$

removals ($R^2 = .29$, $d = 1.59$)

$$(2) \quad R_t / BA_{t-1} = .01702 - .000329 \text{ NGD2}_{t-1}, \quad (8.50) \quad (-2.79)$$

where TA is total acres and NGD is grower net return for raisin-type grapes dried and crushed (prices less unit costs), deflated by the gross national product deflator ($GNPD$). Averages over

three-year ($NGD3$) and two-year ($NGD2$) periods were the best predictors among alternative lag specifications. The low R^2 value for the removal equation and the high significance of the intercept reflect the dominance of nonprice factors in removal decisions.

Block 2. Allocation of Raisin-Type Grapes

Raisin grapes are utilized for drying (1963–85 average = 52.8%), crushing (34.9%), canning (2.5%), and selling fresh (9.8%). Cultural practices for fresh market grapes restrict switching between raisins and fresh sales in the short run and the minor sales for canning could not be modeled separately. Fresh market production (QF) and sales for canning ($QCAN$) were treated as exogenous with the balance of production (Q) allocated endogenously between drying (QR) and crushing (QC).

At the time growers make their allocation decisions, the demand for raisin grapes to crush is known but that for raisins is not. In a purely competitive environment, growers would allocate Q so as to achieve equivalent expected net returns in both outlets, given the observed demand for grapes crushed and the projected demand for raisins. The static competitive (reduced-form) solution would express QR as a function of Q , the demand shifters for grapes crushed, and the expected values of demand shifters for raisins. However, because of the reserve pool operations of the marketing order and the bargaining activities of the RBA , prices received by growers for grapes dried ($PGRD$) have often exceeded the crush price ($PGCD$) by substantially more than would be expected based on differences in costs. Hence, the competitive allocation model seems inappropriate.

An alternative procedure is to view the allocation process as a conditional supply relationship. The quantity of raisin grapes converted to raisins (QR) is expressed as a function of Q , net return to crush, expected net return to grapes dried, and a lagged value of QR reflecting a partial adjustment process.

In forming their expectations of returns from raisin production, growers are assumed to be forward looking, giving consideration to expected supply and market conditions. However, because of difficulties in forecasting the outcomes of RAC and RBA actions and domestic and world demand for raisins, the dominant factors affecting expected net returns for raisins appear to be the size of the raisin grape crop avail-

³ A very small proportion of plantings may be removed before reaching bearing age, but for simplicity this is assumed to be zero.

able for crushing and drying (Q) and recent profit experience. For the latter, a three-year average of past net grower returns (deflated) per ton of grapes dried ($RRD3$) was the best predictor among alternatives considered.

The demand for raisin grapes crushed is influenced by a number of factors not of direct interest in this study, other than to account for their aggregate effects on the price of raisin grapes crushed. Therefore, our estimate of the derivative of the grower crush price ($PGCD$) with respect to quantity of raisin grapes crushed (QC) was obtained from an econometric study of the wine industry by Wohlgenant. The variations in the wine price unexplained by the Wohlgenant coefficient enter the model as exogenous disturbances.

To account for simultaneity, the allocation-to-dry equation was estimated by instrumental variables where the instruments are the predetermined variables Q_t , $RRD3_{t-1}$, QC_{t-1} , QR_{t-1} , $GCWD_t$, $PGCD_{t-1}$, and a constant. $GCWD$ is a measure of deflated cost per ton to produce raisin grapes for crush, and other variables are as defined above. The empirically estimated allocation system is (t -statistics in parentheses) as follows:

Raisin allocation ($R^2 = .89$, Durbin $h = .638$)

$$(3) \quad QR_t = -444,439 + .6037 Q_t + 2178.9 RRD3_{t-1} - 4791.4 (PGCD - GCWD)_t + 0.2623 QR_{t-1} \\ (-1.60) \quad (4.45) \quad (1.81) \quad (-1.99) \quad (2.06)$$

Crush demand

$$(4) \quad PGCD_t = PGCD_{t-1} - .000045(QC_t - QC_{t-1}).$$

Crush allocation

$$(i) \quad QC = Q - QR.$$

Block 3. Allocation and Pricing of NTS Deliveries

The quantity of NTS raisins delivered (DEL) is obtained by multiplying QR , determined in block 2, by a conversion factor. The RAC allocates DEL between "free" tonnage (QFR) and a reserve pool (RES).⁴ In short-crop years, all production may be declared free. The marketing or-

der lists several factors to be considered by the RAC in establishing QFR (NFK, p. 13). Significant predictors of the RAC free tonnage decisions are, on the supply side, deliveries (DEL) plus stocks carried in from the previous year in the reserve pool (CI) and in the hands of packers (SP); on the demand side, previous year packer price for raisins (PD), domestic movement (QD), and a variable (X) to account for a shift in the perception of the export market beginning in 1977. Before 1977, raisin exports were regarded primarily as distress sales from the reserve pool (except in short-crop years). With the strengthening of export markets in the mid-1970s, the RAC shifted its policy to view exports as free tonnage to be sold in regular channels. This shift is modeled by assigning X a value of zero before 1977; the value of lagged total exports (QXT_{t-1}) was used thereafter.

The price packers pay growers for free tonnage is determined by the bargaining process between independent (non-co-op) packers and the grower RBA. The bargaining structure suggests that a competitive farm-level demand function may not be defined and unique market equilibrium solutions may not exist. However, following French (1987), consistent predictions of the (deflated) price outcomes of the bargaining process (PFD) are obtained with a func-

tion that includes essentially the same explanatory variables as would be contained in a competitive grower-level raw product demand function: (a) the free tonnage quantity (QFR) and (b) expected packer net returns in the forthcoming market year, determined primarily by lagged FOB prices and costs, total carryover stocks, and the variable X to account for the policy shift about exports.

Because of (mostly small) inconsistencies in the reports of packer carryin stocks (SP), the identity which relates actual carryin stocks to the previous year's beginning stocks plus quantity packed less sales is replaced by a stochastic equation in the same variables. This equation predicts reported free carryin stocks in the hands of packers. Reported stocks enter the information set in place of actual but unobserved stocks.

The stochastic equations plus key identities which complete block 3 are as follows (t -statistics in parentheses):

Reported stocks ($R^2 = .97$, Durbin $h = -.265$)

⁴ Besides the initial RAC free tonnage declaration, packers may purchase additional tonnage from the reserve pool as the marketing year progresses, for which they pay the free tonnage price plus interest and storage charges. The variable QFR is defined to include both the RAC initial declaration and additional purchases.

$$(5) \quad SP_t = -5873.1 + .904 QFR_{t-1} + .923 SP_{t-1} - .848 (QP + QB + QXF)_{t-1} \\ (-1.30) \quad (11.85) \quad (13.21) \quad (7.58)$$

Free tonnage ($R^2 = .85$, $d = 2.02$)

$$(6) \quad QFR_t = -34,531 + 39.84 PD_{t-1} + .78 (QP_t + QB)_{t-1} - 1.92 SP_t \\ (-.76) \quad (2.98) \quad (2.02) \quad (-4.05) \\ + .40 (DEL + CI)_t + 1.59 X_t \\ (6.38) \quad (3.89)$$

Free tonnage price ($R^2 = .79$, $d = 2.07$)

$$(7) \quad PFD_t = 890.52 + .431 (PD - APCD)_{t-1} - 1.00 (QFR/N)_t \\ (7.77) \quad (4.15) \quad (-4.94) \\ - .19 (SU - QFR)_t/N_t + .0064 X_t \\ (-1.40) \quad (4.67)$$

Reserve carryover

(ii)

$$CI_t = DEL_{t-1} + CI_{t-1} - QFR_{t-1} \\ - QXR_{t-1} - OT_{t-1}$$

Total supply

$$(iii) \quad SU_t = DEL_t + SP_t + CI_t$$

Reserve pool quantity

$$(iv) \quad RES_t = DEL_t + CI_t - QFR_t$$

where variables not otherwise identified are QP and QB , sales in the domestic market (U.S. plus Canada) in package and bulk forms, respectively; QXF , free tonnage exports; QXR , reserve pool exports; PD , the weighted average price for QP and QB sales (deflated by GNPD); $APCD$, the deflated weighted average processing cost per unit for QP and QB ; N , U.S. plus Canadian population; and OT , reserve pool quantity disposed of in other (noncommercial) uses.

Equation (5) was estimated by ordinary least squares. Because the RAC establishes QFR before the grower price (PFD) is bargained for, QFR enters (7) recursively. Equations (6) and (7) were estimated as seemingly unrelated regressions because of likely contemporary correlation of the disturbances.

Block 4. Processed Product Pricing and Demand

Following French and King (1986), packers are viewed as price setters where the FOB price of raisins is set to cover processing plus raw product cost, with further adjustment based on current market conditions, primarily in the domestic market (evidence of such pricing behavior is

provided in NFK, p. 16). Quantities not sold at the offered price are carried to the next season [reported stocks are predicted by equation (5) in block 3].

The price packers set for exports has varied over time according to the export policy adopted by the RAC. In periods of no exports from the reserve pool (1977–80 and short-crop years), the export price was the same as the FOB domestic packer price for bulk raisins (PB) since most exports are in bulk form. During the periods 1963–76 and 1981–85, excluding years with no reserve pool, the RAC sold reserve pool raisins to packers for export at prices such that the weighted average undeflated export price to growers for free and reserve pool exports (PGX) was less than the free tonnage price in nominal dollars (PF); in other years $PGX = PF$. PGX was found to be closely related to the dollar price for Greek raisins in the United Kingdom (an indicator of the world price level for raisins) and the supply of raisins divided by N . The undeflated packer export price (PX) is PGX plus the nominal packer-grower margin for domestic bulk raisins ($PB-PF$).

The price of U.S. raisins in each importing country was computed by adding a transfer cost to PX , then multiplying by the ad valorem duty charged in that country and the U.S. exchange rate with that country, and deflating by that country's CPI. Each foreign market demand function was expressed with per capita sales of U.S. raisins in country I , $QC(I)$, as a function of the deflated price of U.S. raisins in I , the price of competing raisins in I and the per capita deflated income in I .

The price establishment equations, the domestic and foreign demand functions, and the identities and technical relations required to complete the model form a large simultaneous

system in which the predetermined and exogenous variables exceed the number of observations. To deal with this undersize sample problem, the system was divided into two somewhat recursive sub-blocks. Because the FOB price for bulk raisins (PB) is dominantly influenced by variables within the domestic sub-block, it was treated as predetermined with respect to the export sector. The domestic sub-block was estimated by three-stage least squares. In the export block, the PGX equation and the foreign demand equations were estimated as seemingly unrelated regressions. The estimation results are as follows (D appended to price variables indicates deflated value):

Domestic Price Setting and Demand System

Package price ($R^2 = .96$, $d = 1.60$)

$$(8) \quad PPD_t = -458.29 + 1.33 (PCPD + PFD)_t - 1148.3 (QP/SU)_t$$

(5.11) (21.06) (3.99)

Bulk price ($R^2 = .96$, $d = 2.25$)

Japan (J) per capita demand ($R^2 = .67$, $d = 2.48$)

⁵ A variable to reflect the effects of advertising expenditures under the state marketing order and by large packers such as Sun Maid was not included because the effects were thought to remain at about the same general level throughout the period of the data set. The highly successful "dancing raisins" advertising program appeared after the period of analysis.

$$(17) \quad QCJ_t = 252.52 - .00058 \text{ PUJD}_t \\
\begin{matrix} (6.22) & (-6.86) \\ + .0024 \text{ PAJD} - .0001 \text{ EJD}_t, \\ (1.66) & (-1.64) \end{matrix}$$

Total U.S. exports

$$(vii) \quad QXT_t = \sum_I QC(I) \cdot N(I)_t [1 + ROW_t]$$

Variables not previously defined are: PGR , the price of Greek raisins per metric ton (mt) landed in London, nominal dollars; $PG(I)D$, the deflated price per mt of Greek raisins landed in European importing country I , in country I 's currency; $PAJD$, the deflated price of Australian raisins landed in Japan in yen per mt; $TU(I)$, transportation cost from the U.S. to importing country I ; $D(I)$, ad valorem duty plus one, $E(I)$, country I -to-U.S. exchange rate, and $CPI(I)$, country I 's consumer price index; $E(I)D$, deflated per capita income in country I ; and ROW , the ratio (exogenous) of U.S. exports to the rest of the world to exports to the five country groups. The price computed for the Netherlands is used for the Netherlands-Belgium group; the price computed for Sweden, the Sweden-Norway-Denmark group. The negative coefficients for $E(I)D$ in the UK, S and J may reflect a substitution of fresh fruit for dried as incomes have risen.

The equations or rules required to predict the quantity of raisins exported from the reserve pool under the various RAC export policies are not reported here because of space limits and because they are not directly required in the simulations which follow (see NFK, p. 18).

Simulation Analysis

The estimated equations of the four blocks, together with the identities which define the net return variables, form a complete system which, given the values of an initial set of lagged endogenous variables and all values of the exogenous variables, may be solved sequentially for the predicted values of the endogenous variables for all future years. This sequential simulation is used to explore the question, What might have happened if the reserve pool provision of the federal marketing order for raisins had been terminated in 1963, effective in 1964, with all other aspects of the economic environment the same? (1963 was the first year of complete data.) The estimated disturbances of the stochastic equa-

tions are entered as exogenous variables and remain the same with and without the volume control in effect, except as noted. Thus, the sequential solution of the historical model (volume control in effect) generates exact predictions of the observed values of the endogenous variables with which to compare predictions of the no-volume-control scenarios.

Modifications for No-Volume-Control Conditions

If the volume control provision of the federal marketing order were terminated, equation (6), which predicts free tonnage (QFR), would be dropped since there would be no reserve pool and all production would be "free." Equation (12), which predicts the average grower export price (PGX), would be replaced by the identity $PGX = PF$, where PF , is the undeflated free tonnage price. There is little reason to expect that the demand function for raisin grapes for crushing (4), the domestic demand for NTS (10) and (11), or the foreign demand functions, (13) through (17), would differ without volume control. The advertising program under the separate state marketing order (with effects implicit in the estimated demand parameters) is assumed to remain in place with roughly the same general impact. The marketing order does not impose restrictions on packer marketing of free tonnage NTS , so packer FOB pricing practices, (8) and (9), seem unlikely to change significantly; nor would (5) which predicts reported packer carryin stocks. However, four equations—(1), (2), (3) and (7)—might change without the volume control program.

French and King (1988) found that the rate of planting response for a given level of profitability dropped by as much as 45% after the cling peach volume-control marketing order program was terminated. This result suggests a range of alternative scenarios for equation (1). Because French and King found no change in the relation of removal rates to net returns when the peach volume control ended, equation (2) will remain unchanged.

The process of bargaining between packers and the grower bargaining association is assumed to continue without the reserve pool program, with outcomes still predicted by equation (7). However, because all raisin production would be "free," the quantity of NTS produced (DEL) would replace QFR .

If the risk associated with raisin production is

perceived to increase in the absence of the volume control, it is possible that growers would allocate relatively more raisin grapes to the more certain crush market. Therefore, the analysis includes scenarios that tilt the raisin grape allocation equation (3) slightly toward the crush market.

In years of large crops, the RAC set free tonnage (QFR) below DEL , which maintained the free tonnage price of raisins (PFD) generally above equivalent returns per ton of grapes in the crush market ($PGCD$). With a mean ratio of 5.4 short tons of raisin grapes per packed-weight metric ton of raisins, $PFD = 5.4 PGCD$ gives the same gross return per ton for grapes in either outlet. However, 5.4 does not account for the differences in cost and risk factors between the dry and crush outlets. Historically, the actual ratio $PFD/PGCD$ has varied from seven to fifteen.

Without the reserve pool to limit marketable raisin tonnage, PFD as predicted by (7), could be driven to very low levels. However, because growers know the crush demand situation and have Crop Reporting Service estimates of the size of the raisin-grape crop and can observe the current raisin market when they make their allocation decisions, they would not be likely to produce so many raisins that net returns would fall much below those in the crush market. Therefore, the no-volume-control simulations impose a restriction such that $PFD \geq K(PGCD)$, where K sets the minimum ratio of PFD to $PGCD$. If the initial simultaneous solution for grapes dried (QR) and crushed (QC) involving (3), (4), and (i) in block 2 results in $PFD < K(PGCD)$, (3) is eliminated. Equations (4) and (7), with DEL in place of QFR and DEL related to QR by a conversion ratio, are solved simultaneously for QR and QC subject to $QR + QC = Q$ and $PFD = K(PGCD)$. A value of $K = 7$ is assumed for the first no-volume-control run of the model. Because higher values of K might be appropriate if raisin growers viewed production as more risky without volume control, simulations with $K = 8$ and $K = 9$ are also run.

Yields, which are entered at historical annual values in all simulations, could be affected by the change in age distribution of vines resulting from changes in planting and removal rates without the reserve pool program; however, the effect is likely to be minor since yields are primarily determined by weather, diseases, and other natural factors. The quantity-to-fresh use, QF , which has averaged only about 10% of raisin grape production, could also vary in response to

changes in returns to dry and crush. However, because of costly changes in cultural practices required to switch from dry to fresh and the potential price effects in the fresh market, it is unlikely that this proportion would change significantly. Finally, without the volume control program, administrative costs of the marketing order would be reduced. A substantial portion of the grower assessment, which averages about 1% to 1.5% of grower costs, covers costs of providing market information to growers. To maintain a consistent environment, we assume the assessment for economic information would continue. The reduction in assessment resulting from elimination of reserve pool accounting would be such a small percentage of the unit cost of raisin production that no adjustment was made in the representative cost series.

No-Volume-Control Scenarios

With the above considerations, we have specified nine alternative scenarios that could plausibly reflect conditions without the reserve pool program.

Scenario 1: Planting and removal equations, (1) and (2), and the raisin-grape allocation equation (3) remain as in the historical model. The minimum ratio of the free tonnage price of raisins (PFD) to the grower price for raisin grapes crushed ($PGCD$) is set at 7 (i.e., $K = 7$). This restriction becomes binding in years of relatively large crops.

Scenario 2: Same as scenario 1 except planting response (including the disturbance) is reduced by 20% to reflect grower perceptions of increased risk without the marketing order.

Scenario 3: Same as scenario 1 except planting response is reduced 40% [roughly the findings of French and King (1988) for cling peaches].

Scenarios 1A, 2A, and 3A: Same as scenarios 1, 2, and 3 except (a) $K = 8$ to reflect a possible increase in perceived risk for raisin production without volume control and, therefore, a higher reservation price (effective in large-crop years) and (b) the coefficient of Q in equation (3) is reduced by .05 (from .6037 to .5887) to reflect an equivalent increase in risk perception for raisin production in years of small crops.⁶

Scenarios 1B, 2B, and 3B: Same as scenarios

⁶ Decreasing QR by .015 Q has roughly the same average effect on the allocation between drying and crushing as increasing K from seven to eight.

1, 2, and 3 except (a) $K = 9$ and (b) the coefficient of Q in equation (3) is reduced by .03 (from .6037 to .5737).

While no empirical observations are available to establish the range of scenarios A and B, the two variations provide a basis for evaluating both the general magnitude and direction of further changes in allocation response.

Simulation Results

Table 1 gives the time paths of three key indicators of the state of the industry with the volume control program in effect and as predicted without volume control, under three different planting response scenarios. For each scenario, bearing acres (BA) remain the same as under the volume control program for the first two years. However, without the reserve pool to absorb part of the raisin production, the grower price for raisin grapes allocated to drying ($PGRD$) and the representative measure of the average net return

to growers for raisin grapes dried and crushed (NGD) decline sharply.⁷ This leads to reduced plantings and slightly increased removals, which begin to affect bearing acres (and total production) in 1966. In 1967, a year of low yield and therefore no reserve pool allocations, the predicted grower price and net return per ton are higher under the no-volume-control scenarios than actual levels because of lower production from the reduction in bearing acres.

As time moves forward, the reduced returns of the first few years without the reserve pool lead to continued reductions in plantings and

⁷ $PGRD$ is a weighted average of the deflated free tonnage price and the grower export price. That is, $PGRD = [PFD(QP + QB) + (PGX/GNPD) \cdot QXT] \cdot C / (QP + QB + QXT)$, where C is the conversion ratio between metric tons of raisins (packed weight basis) and short tons of grapes used for raisins. Without the volume control program, $PGRD = PFD \cdot C$.

$NGD = [QR(PGRD - GCRD) + QC(PGCD - GCWD)] / (QR + QC)$, where $GCRD$ and $GCWD$ are representative unit costs of producing grapes for raisins. Since our cost estimates may not reflect the precise level of average industry experience, return measures are only indicators.

Table 1. Model Predictions of Three Indicators of the State of the Raisin Industry, 1964–85: Actual Values Under the Volume Control Program Compared with Values Under Three Levels of Planting Response without Controls

Year	Bearing Acres (BA), 1,000s				Grower Average Price for Raisin Grapes to Dry ($PGRD$)				Grower Average Net Return to Dry and Crush (NGD)

^a If reserve pool sales of raisins in noncommercial channels are included in the grower average price computations with the unknown return arbitrarily valued at a deflated price of \$55 per short ton (approximately the price at which raisins were sold to packers under the export incentive program in effect in the early 1980s), the mean values of the grower return variables in the "actual" column are reduced as follows: $PGRD$ from 108.6 to 104.0 and NGD from 0.0 to -1.8. Deflated values may be expressed in 1985 dollars by multiplying by 2.35.

higher removals. Bearing acres fall about 15,000 below the historical level by 1975 for scenario 1 and slightly more under the reduced planting response assumed for scenarios 2 and 3. The differences in *BA* between actual and no-volume-control values narrow somewhat in later years under scenario 1, but widen under scenarios 2 and 3 which assume reduced planting response without the volume control program. Predicted production changes are proportional to bearing acres and variable yields, but under the no-control scenarios, relatively higher shares of raisin grape production are allocated to crushing in most years. By the decade of the 1970s, the reduced acreage and production under the no-volume-control scenarios bring the average grower return to or above the general level of returns with controls. However, returns without volume control again fall below the historical values in 1983–85.

If removal rates should increase without volume control, bearing acres would be reduced further in the early years, with some later modification resulting from feedback into the planting response. Because it seems likely that the overall effects would be contained within the general range of the three planting response scenarios, no specific scenarios involving removal variations are presented.

Table 2 presents the 1964–85 means and standard deviations of actual and predicted values for a larger group of variables and for the full set of alternative no-volume-control scenarios.⁸ Among the nine scenarios, note that for a given value of *K*, means of bearing acres and the output variables decrease with assumed reductions in planting response (*S2*, *S3*) and correspondingly the mean levels of prices and grower average net returns increase. As *K* increases, the allocation of grapes to dry declines as that to crush increases, leading to increases in grower and packer prices for raisins, decreases in the grower price for grapes crushed, but to increases in the combined indicator of grower average net return to dry and crush.

Table 2 suggests the following main effects

on prices, net returns, sales, and stocks of terminating the volume control program:

(a) The mean value of the average grower price for raisin grapes used for drying (*PGRD*) declines under scenario 1 but increases under all other scenarios. The standard deviation of *PGRD* increases about 30%.

(b) The mean price received by growers for raisin grapes crushed (*PGCD*) decreases slightly under most scenarios; the standard deviation increases only about 8%–10%.

(c) The mean value the deflated grower net return per ton of grapes, as measured by *NGD*, is reduced for all scenarios except where planting response is reduced by 40% (scenarios *S3*, *S3A*, *S3B*). The increase in standard deviation ranges from 16% for scenario 3B to 29% for scenario 1. Five years, 1965, 1966, 1983, 1984, and 1985 show losses much greater than ever experienced under the volume control program (see table 1).

(d) The mean value of the average FOB price received by packers (*PD*) increases slightly in scenario 1, but more in scenarios 2 and 3 under reduced planting response. The standard deviation of *PD* increases in the range of 17% to 24%.

(e) Most of the reduction in raisin production under the no-control scenarios was felt in exports rather than domestic shipments. Exports decreased in the range of 10% to 23%, depending on the scenario. The mean level of total carryover stocks decreased without volume control, but all these stocks would be held by packers since there would be no reserve pool (*CI* = 0). (Under volume control, mean level carryover stocks held by packers was $\overline{SP} = 29.4$, while that held by growers in the reserve pool was $\overline{CI} = 20.0$.)

(f) The packer net profit margin (*NPM*), computed by subtracting measures of representative unit packing cost and the cost of the raw product from the FOB packer prices in packaged and bulk form, was both lower and less variable under the volume control program.⁹ As may be observed from equations (8) and (9), the profit margin is affected by the ratios of raisin movement (Q^P , QB) to total raisin supply (SU). Under the marketing order, the total supply is larger relative to movement than without controls. In view of the potential market impact of this larger supply, packers set FOB prices rel-

⁸ In addition to the measures presented in table 2, approximate changes in economic surplus, as indicated by the areas under the demand curves facing processors, could be calculated. However, since over half of the raisins are sold in bulk for use in other food products and for export, interpretation of the surplus measures would be difficult. The value of such calculations is further limited because the model does not encompass the demand and supply systems for alternative crops grown on land shifted from raisin production. A complete examination of the demand, supply and marketing system for wine would also be needed.

⁹ $NPM = [NPMPCQP + NPMB(QB)] / (QP + QB)$, where $NMPM = PPD - PCPD - PFD$, $NPMB = PPD - PCBD - PFD$, and $PCPD$ and $PCBD$ are measures of packing cost per metric ton.

Table 2. Means (Standard Deviations) of Selected Variables Under Volume Control and Alternative No-Volume-Control Scenarios, 1964-85

Variable (s. t. = short ton, m. t. = metric ton)	Actual Data	No-Volume Control Scenarios								
		K = 7			K = 8

Domestic shipments of packaged and bulk NTS (QD) (1,000 m. t.)	118.2 (21.4)	118.0 (25.7)	117.1 (25.3)	115.8 (24.4)	117.1 (25.7)	116.1 (25.3)	114.9 (24.5)	116.1 (25.6)	115.1 (25.3)	113.9 (24.6)
NTS exports (QXT) (1,000 m. t.)	45.6 (13.0)	39.4 (15.3)	38.5 (15.2)	37.2 (14.8)	38.3 (15.0)	37.3 (14.8)	36.1 (14.5)	37.0 (14.8)	36.0 (14.6)	34.9 (14.2)
Total carryover stocks (SP + CI) (1,000 m. t.)	49.9 (37.0)	38.6 (41.3)	36.6 (38.8)	34.1 (34.8)	37.8 (40.1)	35.8 (37.5)	33.4 (34.1)	36.5 (38.4)	34.7 (36.1)	32.6 (33.3)
Packer net margin for NTS (NPM) (1971-72\$ per m. t.)	45 (128)	103 (160)	111 (161)	122 (160)	109 (158)	118 (159)	129 (159)	117 (157)	126 (158)	136 (159)

Note: The means for PGRD, PGCD, PD, NPM, and NGD are simple averages of annual values. The quantity-weighted means are slightly lower but the relationship among actual and scenario values remains essentially unchanged. Also see footnote a, table 1.

actively lower for given raw product prices. The packer net margin was also more variable without the volume control program (the standard deviation increased about 25%) because of an increased variability in FOB packer prices relative to grower prices directly related to the increased variability of supply (*SU*).

Conclusions and Policy Implications

As with any econometric model, the empirical results are affected by the choice of equation forms, the specifications of participant expectations, and the estimation methods. The estimated model is an acceptable representation of the raisin industry in that it is based on generally accepted theoretical criteria and plausible behavioral assumptions, the parameter estimates are consistent with theoretical expectations, and the model tracks the historical system reasonably well. The most challenging aspect of the study is the modification of the model to reflect conditions that would have existed without the volume control program in effect, since such conditions are not observable historically. A set of scenarios was specified to reflect a range of possible no-control conditions. While the validity of these scenarios cannot be tested, their plausibility provides a basis for reaching tentative conclusions about the social costs and benefits of the reserve pool program using the performance criteria proposed by the USDA study team.

Criterion (1): above-normal profits. The measure of grower net return (*NGD*) averaged zero under the volume control program, suggesting that profits were not above normal. However, the representative cost series, while indicating changes in costs over time, may not fully reflect industry-wide averages. As table 1 shows, net returns varied considerably over time, and were affected by many factors besides the volume control program.

Criterion (2): price variability. Prices were less variable under the volume control program than for any of the no-control scenarios.

Criterion (3): disproportionate burdens. This analysis provides no information about possible

disproportionate burdens on particular classes of farmers.

Criterion (4): chronic surpluses. The average level of production was higher under volume control than for any of the no-control scenarios. This extra production can be viewed as "surplus" only if it results in returns persistently below competitive levels or continually requires low-use disposal of part of the crop. Grower returns under volume control, when most reserve pool quantities were either exported or carried over to be sold later, were above returns under most no-control scenarios. However, the higher average quantities carried from one year to the next ($SP + CI$) under volume control suggest a small increase in real marketing cost, which was not measured in the analysis. Significant diversions to noncommercial outlets (school lunches, needy persons, livestock feed, distilling) occurred in years of large crops, averaging about 4% of raisin production overall. These diversions could be regarded as surpluses, but perhaps not "chronic" in the sense intended by the USDA team.

Criterion (5): waste of resources. Resources used to produce raisins diverted to noncommercial use could be viewed as "wasted" because the returns generated are usually below cost. Most such diversions were in years of low or negative return as measured by *NGD* (table 2). The USDA study team argued that a marketing order may reasonably grant producers the right to withhold or divert quantities that would drive returns further below costs. Therefore, the diversions could be viewed as adjustments to unplanned short-run output variations.

Criterion (6): net revenue to growers. While the variable *NGD* is an imprecise measure of the level of grower net returns, relative comparisons indicate that mean returns were higher under the marketing order except for Scenarios 3, 3A, and 3B which assume substantial reductions in raisin supply response. Hence, it would be difficult to conclude that average grower net revenue was reduced because of the marketing order.

Criterion (7): consumer prices. Because the mean of the average FOB packer price (*PD*) is either about the same or above the historical mean for all no-control scenarios, the analysis sug-

gests that the marketing order program did not result in higher average prices to consumers, irrespective of the level of cost.

The mostly static theoretical studies of price stabilization have been generally critical of such programs. The dynamic empirical analysis presented here indicates that consumers were not made worse off in terms of average prices paid and quantities purchased (they may have been better off) and that the program reduced the variability of prices and returns. Grower average net returns may or may not have been increased, depending on the no-control scenario considered, but the marketing order clearly provided some protection in years of unexpectedly large production relative to demand. Overall, the results of the study suggest that the public interest may have been well served by the raisin volume control program, or at worst, there was no significant welfare loss.

Are Farrowing Intentions Rational Forecasts?

David E. Runkle

This paper tests whether quarterly data on hog farmers' sow-farrowing intentions released in *Hogs and Pigs* are rational forecasts of actual farrowings. The empirical results show that neither one- nor two-quarter-ahead intentions are rational forecasts. Econometric methods and the implications of the empirical results for the rational expectations hypothesis are also discussed.

Key words: expectations, livestock forecasts, rationality tests.

Every three months the U.S. Department of Agriculture (USDA) releases *Hogs and Pigs*, a summary of the current livestock inventory and breeding intentions of the nation's hog farmers. Farmers, meat processors, and commodities traders examine this report because the news it contains affects their perceptions about future changes in hog prices. Most of the data in the survey reflect the current state of farmers' livestock herds. But the survey also reports the number of sows farmers intend to farrow in each of the next two quarters. Every issue of *Hogs and Pigs* releases the aggregate farrowing intentions of farmers in ten states.

Because hog farmers' farrowing intentions determine their current plans to buy or sell livestock, any discrepancy between their intentions and their subsequent actions can have a direct effect on their profits. Therefore, farmers should be expected to make the best predictions they can about their own future farrowing plans.

Farmers' farrowing intentions thus provide a natural test of the rational expectations hypothesis. Since the work of Muth thirty years ago (1961), some economists have based their models on the assumption that people have rational expectations about future economic events; that is, that people make the best forecasts they can, given what they know. Many authors have tried to determine whether people actually have rational expectations by testing whether the errors in forecasts of aggregate economic time series are systematic. But their critics point out that most people who answer these forecasting sur-

veys have nothing to lose if their forecasts are wrong. These critics argue that any test of the rational expectations hypothesis based on survey data should be dismissed.

But this criticism may appear to have no effect on the validity of testing the rationality of the farrowing intentions data from *Hogs and Pigs* because of the costs that farmers face if they make inaccurate predictions about their own behavior. Farmers may lose money if they make incorrect predictions about their future farrowing plans because it may be costly to change their plans.

But do farmers accurately report their own farrowing intentions? This paper shows that they do not. It shows that farmers' sow-farrowing intentions, as reported by the USDA, are not rational forecasts of farmers' actual sow-farrowing decisions. But the irrationality of these farrowing intentions does not necessarily refute the rational expectations hypothesis because farmers have few incentives to accurately report their intentions.

Other authors have long been concerned with the accuracy of government crop forecasts. However, the results in this paper are the first published tests of the rationality of government announcements of farmers' intentions for production of either livestock or crops. They extend previous work in agricultural economics on the accuracy of government crop forecasts.

Moore's 1917 analysis of government forecasts of cotton production was the first published work to examine the accuracy of government crop forecasts. Gunnelson, Dobson, and Pamperin examined the accuracy of USDA crop forecasts from 1929 to 1970. However, neither of these studies provided a formal statistical test

David E. Runkle is a senior economist in the Research Department of the Federal Reserve Bank of Minneapolis and an adjunct associate professor of finance at the University of Minnesota.

of the unbiasedness of government crop forecasts. Sumner and Mueller come closest to the tests reported here. In a footnote, they discussed statistical analysis of the accuracy of crop forecasts. But it is not clear whether they performed formal tests of unbiasedness. No tests of the efficiency of crop forecasts or intentions announcements appear to have been published.

How Can the Rationality of Farmers' Expectations Be Tested?

Suppose that a farmer has determined how many sows he will farrow k quarters from now. Denote the current quarter time t and the particular farmer, farmer i . Farmer i makes a prediction at time t about the number of sows he will farrow at time $t + k$. His prediction will be called ${}_i f_{i,t+k}^p$, and the actual number of sows he farrows in time $t + k$ will be called $f_{i,t+k}$.

If the farmer's prediction is rational, it is equal to the mathematical expectation of $f_{i,t+k}$, conditioned on what he knew at time t ; that is, ${}_i f_{i,t+k}^p = E(f_{i,t+k} | I_{i,t})$, where $I_{i,t}$ is the information available to farmer i at time t , and E is the mathematical expectations operator. Forecast rationality also implies that the forecast error from the farmer's prediction cannot itself be predicted using information known when the forecast was made.

If they were available, data on the farrowing intentions and actual farrowings of a particular farmer could be used to test whether his intentions were rational forecasts of his actual decisions by running the following regression:

$$(1) \quad f_{i,t+k} = \alpha_0 + \alpha_1 {}_i f_{i,t+k}^p + \beta' X_{i,t} + \epsilon_{i,k}^i$$

where $X_{i,t}$ is any vector of variables in farmer i 's information set at time t , and $\epsilon_{i,k}^i$ is the error term.

Unbiasedness requires that, in a regression without $X_{i,t}$ variables, the coefficients in equation (1) may be restricted to $\alpha_0 = 0$ and $\alpha_1 = 1$. Efficiency imposes the additional requirement that any variable known at time t or before be orthogonal to $\epsilon_{i,k}^i$; that is, the vector $\beta = 0$ for any vector $X_{i,t} \in I_{i,t}$. A farmer's farrowing intentions are rational only if they are both unbiased and efficient.

There are two reasons why tests of rationality cannot be conducted in this simple manner. First, the data in *Hogs and Pigs* do not reveal the intentions or actions of individual farmers; instead, they provide only aggregate data. Sec-

ond, the failure of certain standard statistical assumptions implies that inference based on ordinary least squares regression (OLS) will not be valid, because the OLS estimate of the covariance matrix will be incorrect.

The discussion of equation (1) presented the restrictions implied by forecast rationality for an individual farmer. Suppose N farmers are sampled in each period, and all of those farmers make rational predictions about their own sow-farrowing decisions. In this case, aggregate farrowing intentions should be a rational forecast of actual aggregate farrowing. If aggregate farrowing intentions at time t are denoted as ${}_t F_{t+k}^p = \sum_{i=1}^N {}_i f_{i,t+k}^p$ and aggregate actual farrowings at time $t + k$ are denoted as $F_{t+k} = \sum_{i=1}^N f_{i,t+k}$, then, because of linearity, rationality implies the same coefficient restrictions in the equation

$$(2) \quad F_{t+k} = \alpha_0 + \alpha_1 {}_t F_{t+k}^p + \beta' X_t + \epsilon_{t,k}$$

as it does in equation (1).¹ Therefore, if each individual farmer makes a rational forecast, the aggregate forecast will be rational, as well.

Although individual rationality implies aggregate rationality, the converse is not true. If one farmer always underpredicts his farrowing by fifty sows while another always overpredicts his farrowing by fifty sows, the sum of their forecasts would be unbiased even though neither farmer makes an unbiased forecast. This example illustrates why aggregate data can disprove individual rationality but cannot prove it.

The problems with standard OLS statistical assumptions are somewhat less transparent than the issues of aggregation. Inference based on OLS regressions assumes that the errors in the regression equation are independent over time and have the same variance in each period. Each of these assumptions may be invalid in estimating equation (2). If either assumption is violated, then the OLS covariance matrix will not be a consistent estimate of the true uncertainty in the estimated parameters in equation (2), even though the OLS parameters themselves are consistent estimates of the true parameters.

The first problem with using OLS to estimate equation (2) is that the errors in that equation may be serially correlated. If farmers predict farrowings two periods ahead, then $k = 2$ in

¹ The only difference between the two equations is the interpretation of X_t . In equation (2), X_t can be either data that was publicly known at time t or the sum across farmers or particular pieces of private information that each farmer had. For example, since each farmer would know how many sows he had farrowed in time t , the linearity of equation (1) implies that the aggregate number of sows farrowed in t can be included in X_t .

equation (2). In this case, the farmer's forecast errors can be serially correlated even if their forecasts are rational. Figure 1 demonstrates how this serial correlation could arise and shows how to determine the order of the serial correlation.

Suppose that at time t , a farmer predicts his sow-farrowing intentions for time $t + 2$, $f_{i,t+2}^p$. At time $t + 2$ when his actual farrowings, $f_{i,t+2}$, are known, his two-period-ahead forecast error, $\epsilon_{i,2}^i = f_{i,t+2} - f_{i,t+2}^p$, is also revealed. If the farmer's farrowing intentions announcement is a rational forecast of his actual farrowings, his forecast error should be uncorrelated with anything he knew when he announced his intentions.

For example, figure 1 shows that the error the farmer made at time $t - 2$ in predicting his sow farrowing at time t , $\epsilon_{i,t-2}^i = f_{i,t} - f_{i,t-2}^p$, is known when he announces his intentions at time t for time $t + 2$. Therefore, $\epsilon_{i,2}^i$ should not be correlated with $\epsilon_{i,t-2}^i$ if his farrowing intentions announcement is a rational forecast, because $\epsilon_{i,t-2}^i$ is in the information set $I_{i,t}$.

Figure 1 also shows that the farmer does not know the error he made at time $t - 1$ in predicting his farrowings in time $t + 1$. That error,

$\epsilon_{i,t-1,2}^i = f_{i,t+1} - f_{i,t-1}^p$, becomes known only at time $t + 1$ when actual farrowings for that period, $f_{i,t+1}$ are known. Therefore, even if the farmer's intentions announcement were a rational forecast of his actual farrowings, the farmer's forecast error would be serially correlated because $\epsilon_{i,t-1,2}^i$ is not known when $f_{i,t+1}$ is announced. That is, $\epsilon_{i,t-1,2}^i$ is not in $I_{i,t}$.

Thus, if the farmer's intentions announcement is a rational forecast, $\epsilon_{i,2}^i$ can be correlated with $\epsilon_{i,t-1,2}^i$, but it cannot be correlated with $\epsilon_{i,t-2,2}^i$. This correlation implies that the errors in equation (1) would be moving-average errors of order 1 [MA(1)]. Hansen and Hodrick first demonstrated that this kind of forecast-error correlation would arise in multiperiod forecasts, even if the predictions were rational. The aggregate data in equation (2) should have exactly the same error structure as the individual data if all farrowing intentions are rational forecasts.

Although the errors in equation (2) would be serially correlated if farmers were making two-period-ahead forecasts ($k = 2$), using a generalized least-squares (GLS) transformation to eliminate the serial correlation in that equation would be invalid because the principal regressor

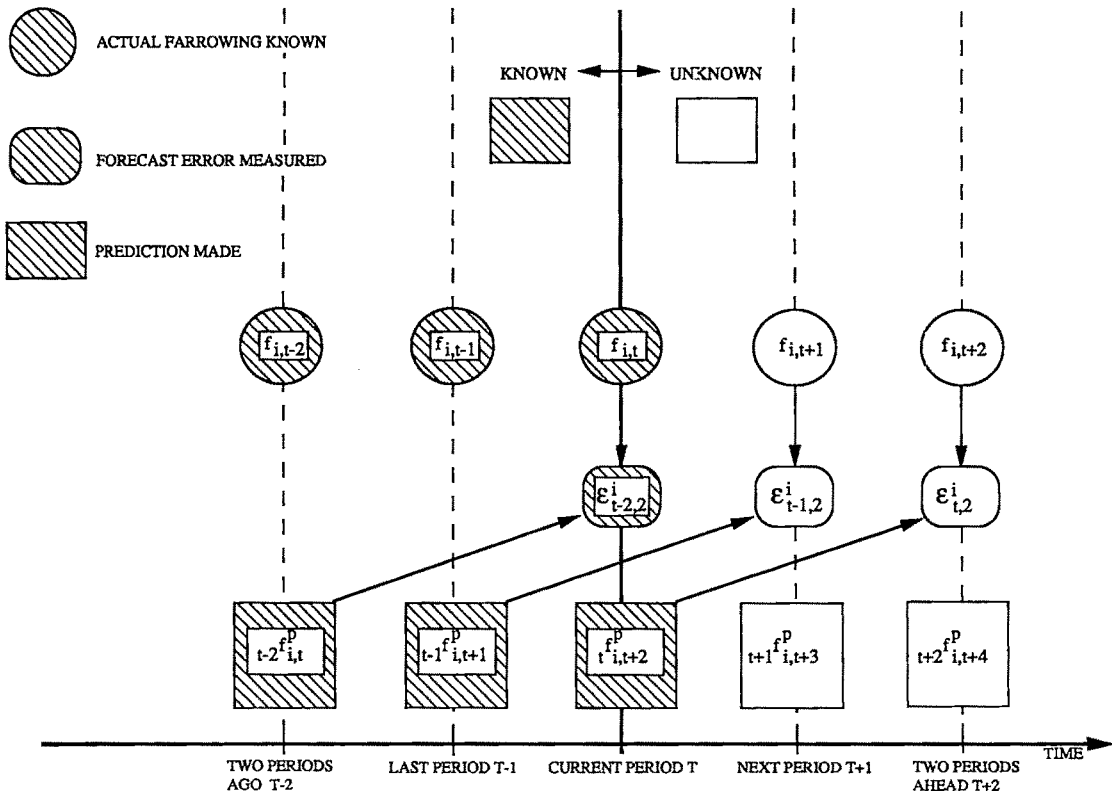

Figure 1. What a farmer knows when predicting his sow farrowings two periods later

(F_{t+2}^p) is predetermined, rather than exogenous. In fact, as Hansen and Sargent show, conventional GLS estimates of the parameters in (2) would be inconsistent because the transformed errors would be correlated with the transformed regressors.² This problem would be even more serious than the misestimation of the covariance matrix that would result from using an OLS regression.

If farmers were making only one-period-ahead forecasts ($k = 1$), moving-average errors would not be present in equation (2). Nevertheless, inference using OLS could still be invalid if the conditional variance of the error were correlated with the regressors. This problem, which White calls conditional heteroskedasticity, often arises in time-series data. If conditional heteroskedasticity exists in the data, then the OLS estimate of the covariance matrix will be incorrect even if there are no moving-average errors.

The problems in inference created both by moving-average errors and conditional heteroskedasticity can both be solved by using Hansen's generalized-method-of-moments (GMM) estimator to perform tests of forecast rationality. Hansen's estimator uses a set of optimally weighted orthogonality conditions to estimate parameters efficiently for most standard econometric models. For equation (2), the orthogonality conditions are that the estimated error is orthogonal to each of the regressors, that is,

$$E((F_{t+k} - (\alpha_0 + \alpha_1 F_{t+k}^p + \beta' X_t))' Z_t) = 0, Z_t \in \{1, F_{t+k}^p, X_t\}.$$

Hansen shows that any GMM estimator takes the following form:

$$(3) \quad \min_{\gamma} g(\gamma)' W g(\gamma),$$

where γ is a vector of coefficients, $g(\gamma)$ is the vector of sample averages of the set of orthogonality conditions specified in a given statistical model, and W is a weighting matrix. In equation

(2), the vector γ is the set of coefficients α_0 , α_1 , and β .

Hansen also shows that the optimal weighting matrix W for a GMM estimator is simply the inverse of the covariance matrix of the orthogonality conditions for that particular equation. If the errors for a particular equation are $MA(p)$, then the estimate of the covariance matrix of the orthogonality conditions is

$$(4) \quad \hat{\Omega} = \frac{1}{T} \sum_{j=-p}^p \sum_{t=1}^T Z_t' \hat{\epsilon}_{t,k} \hat{\epsilon}_{t-j,k}' Z_{t-j},$$

where $\hat{\epsilon}_{t,k} = ((F_{t+k} - (\hat{\alpha}_0 + \hat{\alpha}_1 F_{t+k}^p + \hat{\beta}' X_t))' Z_t)$, and consistent estimates of the parameters are used to form the residuals used in constructing the weighting matrix.

If $\hat{W} = \hat{\Omega}^{-1}$, then the GMM estimator is efficient within the class of estimators that uses only conditional moment restrictions, as was shown by Chamberlain. Because of the moving-average error structure, this estimate is not constrained to be positive definite. Newey and West discuss consistent estimates that are guaranteed to be positive definite. The Newey-West estimator is used in the GMM results presented in this paper.

For this analysis, the GMM parameter estimates are exactly the same as the OLS parameter estimates because equation (2) is exactly identified: the number of instruments and the number of regressors is the same. But the GMM standard errors will be correct in the presence of moving-average errors and conditional heteroskedasticity, while the OLS standard errors will be incorrect. Almost all empirical tests in this paper are therefore based on GMM estimation.

Data and Empirical Results

For almost thirty years, *Hogs and Pigs* has published quarterly aggregate data on sow-farrowing intentions for farmers in ten states.³ These data are gathered through interviews conducted by the USDA. Starting on the first day of March, June, September, and December, USDA interviewers ask farmers how many sows they intend

² Consider the case of testing the unbiasedness of equation (2) when $k = 2$. The equation of interest would be $F_{t+2} = \alpha_0 + \alpha_1 F_{t+2}^p + \epsilon_{t,2}$. Because the error term would have an $MA(1)$ structure under the hypothesis of unbiasedness, assume that that error structure can be represented as $\epsilon_{t,2} = \eta_{t+2} - \gamma \eta_{t+1}$. GLS would require that we filter equation (2) by $(1 - \gamma L)^{-1}$ to get rid of the serial correlation in $\epsilon_{t,2}$. However, this would cause the filtered equation to violate the OLS orthogonality conditions. Note that the transformed regressor would be $F_{t+2}^p = (1 - \gamma L)^{-1} F_{t+2}^p = (F_{t+2}^p + \gamma_{t-1} F_{t+1}^p + \gamma_{t-2}^2 F_{t+2}^p + \dots)$, while the transformed error term would be $\tilde{\epsilon}_{t,2} = (1 - \gamma L)^{-1} \epsilon_{t,2} = (\epsilon_{t,2} + \gamma \epsilon_{t-1,2} + \gamma^2 \epsilon_{t-2,2} + \dots)$. However, we know that $F_{t+2}^p \perp \epsilon_{t,2}$ if, and only if, $j \leq k$. But since the product $F_{t+2}^p \epsilon_{t,2}$ would contain terms like $F_{t+2}^p \epsilon_{t,2}$ where $j > k$, $F_{t+2}^p \not\perp \epsilon_{t,2}$.

³ Until 1968, the title of the report was *Pig Crop Report*. Since 1940, this report has also contained biannual intentions data for farmers in the entire country. The USDA increased the number of quarterly states to fourteen in 1973 but continued to publish data for the original ten states. In 1982 the USDA changed its ten-state sample. Later in this section, the effect of these changes on the tests of rationality is discussed.

to farrow in the next three months, how many sows they intend to farrow in the three months after that, and how many sows they farrowed in the preceding three months.⁴ The survey methods for *Hogs and Pigs* are described in USDA (1977, 1979).

The empirical tests in this paper use aggregate published data on quarterly farrowings in ten states from the first quarter of 1961 until the first quarter of 1989.⁵ The goal of this paper is to test whether the first and second farrowings intentions announcements are rational forecasts of actual farrowings. To see how these tests were conducted, consider the following example. In September 1960 and December 1960, farmers were asked how many sows they planned to farrow between 1 December 1960 and 28 February 1961. In March 1961, farmers were asked how many sows they actually farrowed in the previous three months. The analysis here compares the September and December intentions data to the actual farrowings announced the following March.

Two potential problems with the data need to be addressed before the empirical findings are reported. First, inference using the entire sample could be invalid because the ten-state sample changed in 1982. Second, inference using the initial announcements of actual farrowings could be invalid if those announcements were biased.

To solve the first problem, the observations which would have resulted in comparing intentions data for one set of ten states with actual farrowings for the other set were dropped. Even if the sample of states is changed, as long as the same farmers provide both the intentions data and the actual farrowings data, the tests of rationality are valid.⁶

The second problem was somewhat more difficult to address. If the initial announcements of actual farrowings were revised in a predictable way, then the data used here could result in incorrect inference. One way to determine whether such revisions could affect statistical inference is to check whether the initial announcements of sow-farrowing intentions are rational forecasts of the revised data. Such a test was developed by Mankiw, Runkle, and Shapiro. If the initial

announcement is a rational forecast of the revised data, then using the initial announcement will cause no problems in inference. In fact, GMM estimates show that the initial announcement is a rational forecast for any of the next three quarterly revisions. Therefore, data on the initial announcement of sow farrowings in the past quarter are used as the dependent variable.⁷

Because a prediction must be both unbiased and efficient to be rational, separate tests for unbiasedness and efficiency were conducted. Table 1 shows the results of the unbiasedness tests. The first column of that table shows that the USDA series on aggregate intentions of sow farrowings during the next quarter is an unbiased predictor of actual aggregate farrowings in ten states. Since the hypothesis of rationality imposes two restrictions, if the intentions data were unbiased, the test statistic reported in column 1 should be asymptotically distributed as a chi-square with 2 degrees of freedom random variable. Since its value is only 4.228, the hypothesis of unbiasedness cannot be rejected.

Note that the results in column 1 were based on a GMM estimate of the covariance matrix of the parameters. Column 2 shows that, if the OLS estimate of the covariance matrix were incorrectly used, the hypothesis of unbiasedness would have been incorrectly rejected. This result illustrates the importance of using GMM estimates of the covariance matrix in time-series models. All additional results in this paper come from GMM estimation.

Column 3 shows the results of a test of whether the USDA series on aggregate intentions of sow farrowings in the period three to six months following the survey is an unbiased predictor of actual farrowings during that period. The results in this column show that those intentions are biased predictors and are therefore not rational forecasts of actual farrowings. The chi-square test statistic shows that the hypothesis of unbiasedness can be rejected at the 1% confidence level. This rejection is strong evidence that the two-quarter-ahead announcement of sow-farrowing intentions is not a rational forecast of actual farrowings. In fact, if two-quarter-ahead farrowings were predicted using the regression reported in column 3 instead of the two-quarter-ahead farrowings intentions announcement, the

⁴ For example, in December 1989, farmers were asked "Of the sows and gilts [you are holding in inventory] how many are expected to farrow between March and May 1990," to determine their two-quarter-ahead farrowing intentions.

⁵ Because of the timing of the survey, the first quarter of 1961 is really December 1960 through February 1961.

⁶ As with all tests of rationality using aggregate survey data, the effects of sampling error are ignored.

⁷ The government announcements of actual farrowings are adjusted using data other than the survey. The rationality tests for the initial announcement are not reported here because they are not germane to determining whether farmers farrowing intentions, rather than government data revisions, are rational.

Table 1. Tests for Unbiasedness of One- and Two-Quarter-Ahead Aggregate Sow-Farrowing Intentions

	$F_{t+k} = \alpha_0 + \alpha_1 F_{t+k}^p + \epsilon_{t,k}$		
	(1) One Quarter ($k = 1$)	(2) One Quarter ($k = 1$)	(3) Two Quarters ($k = 2$)
Forecast horizon			
α_0	111.926 (58.026) ^a	111.926 (47.312)	228.628 (70.644)
α_1	0.947 (0.026)	0.947 (0.020)	0.901 (0.031)
Estimation method	GMM	OLS	GMM

Number of observations	111	111	109

^a Standard errors are in parentheses under coefficients.

mean-square forecast error would be reduced by over 10%.

Because the two-quarter-ahead intentions announcements are biased, they are not rational forecasts; therefore, there is no point in testing whether they are efficient forecasts. But since the one-quarter-ahead intentions announcements appear to be unbiased, further tests are warranted to determine whether they are efficient forecasts.

One piece of information that each farmer knows when announcing his one-quarter-ahead intentions is his own two-quarter-ahead intentions from the previous period. In fact, his current one-quarter-ahead intentions are a revision of his previous intentions. If the current announcement of intentions is an efficient forecast, adding the previous intentions as an additional explanatory variable should not improve the accuracy of the forecast.

Table 2 shows a test of this hypothesis. Since β_1 is highly significant, lagged two-period-ahead intentions provide information useful in forecasting that is not included in the one-period-ahead intentions data. The chi-square test shows that the hypothesis of forecast efficiency can be rejected at the 1% level. Therefore, the one-quarter-ahead intentions report is not a rational forecast of actual farrowings because it is not an efficient forecast. If one-quarter-ahead farrowings were predicted using the regression reported in table 2 instead of the one-quarter-ahead farrowings intentions announcement, the mean-square forecast error would be reduced by over 11%.

What Does the Rejection of Forecast Rationality Mean?

These results show that neither the one-quarter-ahead nor the two-quarter-ahead farrowing-intentions announcement in *Hogs and Pigs* is a rational forecast of actual farrowings. But what does this mean? It could mean that farmers are not good at predicting their own actions, but this is probably not the most likely explanation. A farmer would lose money if he did not accurately predict his own future actions, but there is no cost to him if he does not accurately report his intentions.

Although it may be somewhat surprising that farmers announce irrational forecasts of their own future actions, it would be considerably more

Table 2. Test for Efficiency of One-Quarter-Ahead Aggregate Sow-Farrowing Intentions

$F_{t+1} = \alpha_0 + \alpha_1 F_{t+1}^p + \beta_1 F_{t-1}^p + \epsilon_{t,1}$

^a Standard errors are in parentheses under coefficients.

surprising if livestock market analysts were to announce irrational forecasts of farmers' actions. Because the market analysts, unlike farmers, are paid for the accuracy of the forecasts they report, they have a strong economic incentive to report accurately. In fact, Colling and Irwin recently found that the averages of market analysts' expectations about the announcements in *Hogs and Pigs* on reported changes in breeding- and market-hog inventories are rational forecasts. Thus, the different outcomes of these two rationality tests may stem from the different economic incentives that farmers and market analysts have to report their expectations accurately.

These differences in the rationality of reported expectations are paralleled in the economic literature on testing the rationality of inflation forecasts. Carlson and Mullineaux, among others, found that the inflation forecasts in the Livingston survey are not rational forecasts of actual inflation. In contrast, Keane and Runkle found that the price forecasts made by professional forecasters in the American Statistical Association-National Bureau of Economic Research Survey are rational forecasts. They suggest that the nonprofessional forecasters in the Livingston survey may have few economic incentives to accurately report their expectations, and thus, the irrationality of those reported expectations is not surprising.

Because farmers appear to have few economic incentives to report their farrowing intentions accurately, the fact that those intentions are not rational forecasts does not necessarily disprove the rational expectations hypothesis. Nevertheless, this paper has shown that forecasts of actual sow farrowings can be significantly improved by discarding the assumption that the aggregate sow-farrowings intentions announcement is unbiased and efficient.

The Welfare Analytics of Transaction Costs, Externalities, and Institutional Choice

Ronald C. Griffin

A natural result of the economist's participation in externality literature has been a strong emphasis upon market and price-guided policies. Available theoretical foundations are insufficient for supporting this ideology. Absent is a conceptual framework which integrates institutional options and their attendant resource costs with what we know of resource and technology constraints. This paper addresses this omission by incorporating an explicit role for transaction costs into traditional welfare diagrammatics.

Key words: externality, institutions, property rights, resource policy, transaction costs, welfare economics.

Externality and market failure literature of recent decades has been responsible for a substantial amount of discussion, debate, and insight regarding the social relations which bind and, indeed, define mankind. These developments have been spurred in no small part by the policy relevance of externality-like issues. In addition, because economists have believed that they offer valuable input for such issues, market devices for "correcting" externalities have always been emphasized in the literature, often to the exclusion of other social/legal relationships. "When the only tool you have is a hammer, everything looks like a nail." Throughout this literature, concern for the relative abilities of the market and government policy has usually been explicit.

One of the primary themes of the externality literature and its variants should be that a wide array of institutions is available for correcting externalities. While certain camps might focus on narrowly defined subsets of these internalizing institutions, common sense suggests that society examine externality situations on a case-by-case basis and choose the best structure available for accommodating the externality

interdependence. The importance of transaction costs becomes apparent in the pursuit of this objective.

A major tenet of the more recent literature has been the integral involvement of transaction costs within organizational processes which seek to have externality creators account for their impacts upon recipients. These processes include both market and nonmarket forms of internalization, and all such alternatives incur transaction costs to some degree. Literature on this subject observes that markets for accommodating externality problems will naturally arise if transaction costs are sufficiently low (Demsetz 1964, 1967). Moreover, because it is rarely possible to know, a priori, whether market-incurred transaction costs are exceeded by the transaction costs of each policy (nonmarket) alternative, the desirability of policy is usually founded upon subjective biases regarding relative levels of transaction costs (Dahlman).

While transaction costs are usually viewed as affecting the economic efficiency of alternative internalizing institutions, it is not typically acknowledged that transaction costs are also relevant in defining economic efficiency. The prevalence of transaction costs implies that concepts such as Pareto optimality are not immune to a consideration of information and its costs. Even when this fact is suggested, means for operationalizing it are rarely provided. By properly applying some traditional "welfare ana-

The author expresses appreciation to Andy Dragan, Wes Peterson, John Stoll, the *A/AE* reviewers and, especially, Dan Bromley for comments and suggestions.

lytics," an insightful background can be obtained for institutional choice in the presence of transaction costs. The purpose of this paper is to expand neoclassical tools of welfare analysis (summarized by Bator) to accommodate a role for transaction costs.

Definitions and Background

To facilitate the exposition it is useful to establish a few fundamental definitions. It is particularly important to elucidate the concepts of externality, property rights, and transaction costs so that a common basis for the forthcoming discussion can be obtained. With regard to externality, the following definition is adopted and progressively justified in this paper. An externality is an interdependence among people. Externality, as it is defined here, does not imply Pareto relevancy. That is, there is no presumption of social ill in this definition. This definition is not mainstream, for the literature more commonly defines externality as an interdependence among economic actors for which a market or some other compensatory device does not exist (Baumol and Oates, Bromley 1986, Heller and Starrett). This second definition offers instructional utility, which hopefully explains its predominance, but it has the potential to perform great damage in application. While economists have a predilection for emphasizing market absence as a necessary condition for externality, an institutionally unbiased definition allows one to entertain nonmarket allocation processes as potential externality remedies. Casual reflection will isolate numerous social modes of externality resolution. For the most part, these institutions are so broad and permeating that they escape exhaustive classification efforts and, often, even our abilities to identify particular mechanisms.¹ One purpose of this paper is

to assign a greater standing to the diverse array of nonmarket externality-addressing institutions. By directly incorporating transaction costs into the definition of Pareto optimality, the central objective of this paper is to build upon the idea that a Pareto-relevant externality is an externality that is being addressed by the wrong institution rather than not being addressed by any institution (especially markets) at all.

In the course of studying the entirety of institutions relevant to externality interdependencies, insight can be achieved by carefully emphasizing markets. The concept of property rights is crucial here, and, with Macpherson's warning in mind, "the meaning of property is not constant" (p. 1), it is useful to preface forthcoming discussion with a brief sketch of the elements composing property rights. Following Calabresi and Melamed's classic paper, property rights can take the form of property rules, liability rules, or inalienable entitlements.² Protection of one's interest in an interdependence by a property rule infers that one's desires in this relationship are ascendant to the desires of other involved parties unless the protected individual chooses to reassign this control. Similarly, protection via a liability rule in an interdependence provides for compensation should other individuals choose to assume control over the relationship. An inalienable entitlement declares that one's interests in a relationship cannot be legally reassigned or taken under any circumstances even when each party to the interdependence is willing.

Property rules are fundamental to the operation of markets which assign value prior to an interdependence, and liability rules necessitate some form of judicial system to settle value after an interdependence has occurred. Generally speaking, property rules are the foundation of market activity, and liability rules are the basis for litigation. However, sufficiently established

¹A few examples of common interdependence-internalizing institutions may be in order.

Envy is a term representing a specific class of consumption interdependencies among individuals. Envy, therefore, qualifies as an externality given either the above definition or the more traditional "interdependence without a market" definition. Institutions that address this type of interdependence do, however, exist. Society seeks to teach or convince individuals that envy is undesirable, even irrational. In this case the intent of the control institution is to repress the interdependence. Social teachings (e.g., the ninth and tenth Commandments) serve to allocate the costs of envy to the envious themselves. This is conceivably an efficient solution, because the envious may be in the best position to solve the problem—by adapting their utility functions to be less responsive to the interdependence.

A child is dependent on his or her parents for the provision of a positive environment in which to live, learn, and mature. Yet, no

market is available for the interdependence. Instead, parents possess a felt or declared responsibility to bear the burden of the interdependence. The source of these feelings may be partly founded on instinct, but this is assuredly reinforced by the parents' childhood participation in family relationships in addition to the important role of social teachings. It is notable that changes in tastes or relative scarcities may have recently led to dissatisfaction with the ability of family/community/church institutions to internalize the child-parent interdependence. As a result, additional institutions are being tried. Public awareness and opinion regarding child abuse has increased. Child abuse is being more broadly defined. Welfare agencies now act in an oversight capacity, monitoring the performance of parents previously suspected to be remiss in their parental duties. The "rights" of children are being refined to the point that they are better able to serve as the basis for court action brought upon parents by their children or by others.

²This classification is essential to a great deal of literature. See, for example, Bromley (1978), Buchanan and Faith, and Frech.

liability rules also may provide a basis for market transactions, and the ongoing refinement of property rules often occurs in the courthouse. Inalienable entitlements act as constraints on market activity, presumably to advance higher-order social objectives.

In forthcoming discussion, the emergence of markets to address an externality interdependence will be equivalent to the establishment of a property rule. In the simplistic view of this process, society must decide which person or group of persons should be vested with a newly created property rule. The more complex (and more realistic) perspective is that property rules do not emerge into an institutional vacuum but must coexist in an evolved system of, among other things, detailed property rules. Therefore, new property rules are best characterized as additional circumscriptions or alterations within social institutions. The simpler of these two interpretations is not too misleading for the more immediate purposes of this paper.

Transaction costs include "the costs of obtaining information, establishing one's bargaining position, bargaining and arriving at a group decision, and enforcing the decision made" (Randall 1972, p. 176n). Dahlman separates transaction costs into (a) search and information costs, (b) bargaining and decision costs, and (c) policing and enforcement costs and then states that all of these costs "represent resource losses due to lack of information" (Dahlman, p. 148). Moreover, the amount and distribution of transaction costs will differ between property rules and liability rules as well as between situations in which an initial entitlement (either a property or liability rule) is held by one party or another (Bromley 1978).

The Welfare Analytics of Property Rules

It is convenient to introduce the elements of this discussion in a progressive fashion beginning with the establishment of a general externality. Let us temporally adopt, for the sake of argument, the instructional definition: Externalities are interdependencies among economic actors which, for the purpose of the immediate discussion, are not accompanied by markets. A specific act of internalization merely causes the relation to enter into the decision calculus of causal economic agents who previously ignored it in full or in part. The interdependence may involve producers, consumers, or both producers and consumers.

Beginning with a narrow but instructive framework, internalization occurs whenever property rights for the interdependence are erected and allocated by the appropriate legal system. All other rights and institutions are fixed. Of course, legal inaction regarding the property right arrangements which surround a particular interdependence does not imply that there is no presumptive or putative ownership (Samuels and Schmid, Umbeck). Parties probably have some preconceived notions regarding unvalidated ownership claims. The degree of certainty (or uncertainty) attached to these notions is the foundation of present and future social, political, and legal action by individuals. Externality instigators (i.e., those having the physical power, though possibly not the right, to modify the level of an externality) may clearly create the externality in the absence of prior government action. There is nothing to halt such action by instigators nor to force it.

At a later date a liability or property rule may be newly erected or derived from a more general concept (such as the law of nuisance). Recognition of this possibility may enter the instigator's decision calculus as part of his or her preconceptions regarding the validity of the claim. Uncertainty as to the status of claims will motivate some parties, particularly those with better access to processes of institutional change and/or with positive attitudes regarding the validity or worth of their claims, to pressure the social system for a sanctioned declaration of ownership.

As each externality relationship is born, the process begins: the relationship is tolerated, that is, ownership remains presumptive and unsanctioned, so long as the relation is relatively unimportant. Through an evolutionary process the externality grows or fades in relevance to economic actors as a result of gradual and not so gradual changes in preferences, technology, and relative scarcities. Externalities may diminish into obscurity or evolve into important socioeconomic relationships whereby social declarations of property form the basis of an entire market. Alternatively, trade in the interdependence may not be permitted, and legal constraints can be formed to guarantee the absence of trade (inalienable entitlement). And let us not forget that externalities are resolvable by a large array of social mechanisms other than markets: regulations may be enacted, less formal rules of conduct may be formed, economic incentives may be established, and specific liability rules may be promulgated.

To model these concepts first in the absence of transaction costs, consider an evolving production externality in which the production of good X affects the production of one or more other goods in a manner which is unaccounted for by an existing market. Figure 1 depicts a typical production possibility frontier (PPF) exhibiting social transformation opportunities between good X and the monetary equivalent of all other goods. If the evolving production externality is positive, then the PPF will be shifted outward. If the externality is detrimental, then the shift will be inward. In both cases intercepts A and B will be unaltered. In this way, positive externalities increase the convexity of the PPF , and negative externalities decrease convexity (Baumol).

The impact of the production externality on the potential welfare of consumers is illustrated in utility space. Corresponding to each point on the PPF there is a contract curve depicting Pareto-optimal allocations of all goods between any two consumers. Mapping the contract curve in utility space produces a utility possibility frontier (UPF). The outer limit of all UPF 's (one for each point of the PPF) produces the grand utility possibility frontier ($GUPF$). Through its effect upon the PPF , detrimental production externalities will shift the $GUPF$ inward and beneficial production externalities will shift the $GUPF$ outward. Unlike the PPF , production externalities can alter the endpoints of the $GUPF$. For example, in figure 2 the initiation of a detrimental production externality has shifted the $GUPF$ from CD to $C'D'$. On the other hand, a consumption externality will preserve points C

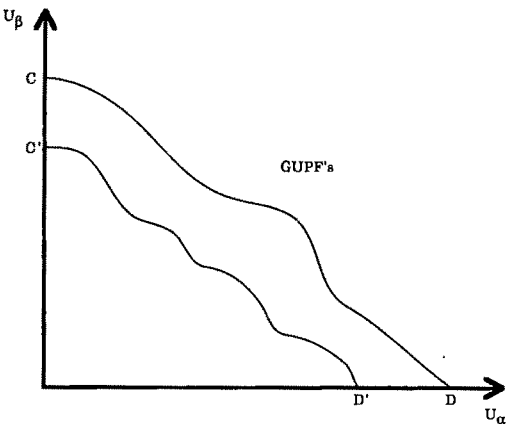

Figure 2. Grand utility possibility frontier shifts for production externalities

and D as endpoints of the $GUPF$. In figure 3, a detrimental consumption externality has produced an inward shift of the $GUPF$. In this latter case, the PPF is unaltered.

The formation of producer \rightarrow consumer externalities may affect the PPF in that consumers may choose to adjust their supplies of production inputs. More important, production at any point along or interior to the PPF will shift the indifference maps of individuals in X - $\$$ space, assuming that the new externality relationship is exogenous to these variables. Contract curves may be affected depending on how indifference maps are shifted, but UPF 's will certainly be shifted. Therefore, the $GUPF$ will be shifted inward or outward in the manner depicted by figure 2.

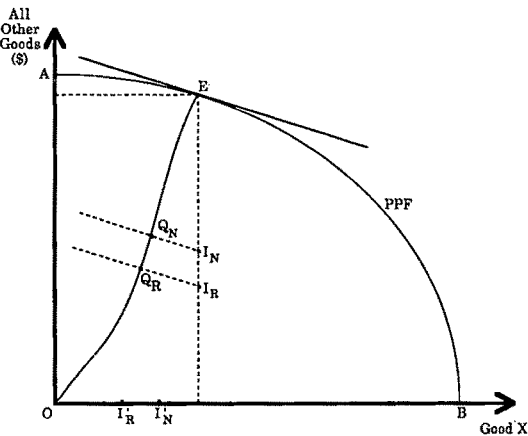

Figure 1. Equilibria for alternative endowments without transaction costs

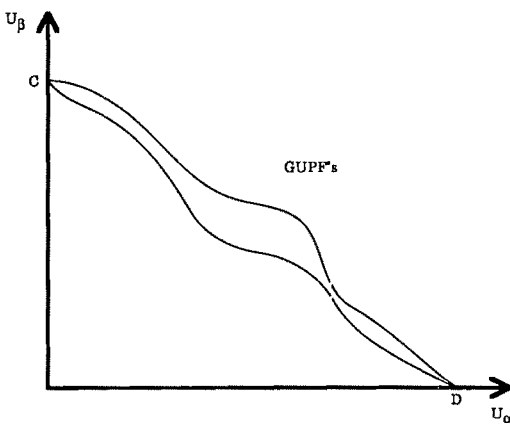

Figure 3. Grand utility possibility frontier shifts for consumption externalities

Suppose that the *PPF* illustrated in figure 1 represents present conditions including the externality. Let us assume that the externality is beneficial and that its instigators (i.e., the producers of X) have the power to produce the externality and that the receptors have no enforceable right to either prevent or force the externality. This initial situation is one of "privilege" favoring instigators and corresponding "no rights" for receptors if legal sanction has not been acquired (Bromley 1989). If legal sanction is obtained, then the situation becomes one of a property "right" for instigators and a corresponding "duty" for receptors (Bromley 1989). Denote this property right as the N (instigator) rule.

The implications of preserving the N rule or adopting its opposite, the R (receptor) rule, has received much attention in the literature.³ This attention has focused almost exclusively on the effect of this choice on the resulting competitive equilibrium and the resulting welfare positions of the economic participants. The following Coasian conclusion is well known and warrants illustration within the above framework: In the absence of private resource constraints, wealth effects, and transaction costs, the Pareto optimality of competitive equilibrium is independent of ownership.

Assume that supply and demand conditions resulting from the initial N rule support a Pareto optimal production equilibrium at point E on the *PPF*. In figure 1 curve OE represents the corresponding contract curve where the economy is assumed to be divisible into two totally homogeneous groups. Group α is composed of the producers of X , all of which have equivalent utility functions. Group β incorporates all others, who are assumed to have equivalent preferences and share equally in their group's net product.

Constructing the Edgeworth box defined by point E , we shall let point O be the origin for the indifference map of group α (the X producers) and point E shall be the origin for group β . After production has been completed, initial endowments will be given by points such as I'_N or I_N . Endowment I'_N will be relevant if X producers have to exchange part of their product to purchase inputs. Endowment I_N will be relevant if X producers own productive factors required by other producers and if the amount of these resources is more than sufficient to acquire the inputs needed for X production.

Within this model, the effect of adopting an R rule to replace the N rule is only to change initial resource endowments. The R rule weakens the welfare position of group α relative to group β regardless of whether the externality interdependence is positive or negative. Thus, the R rule causes new post-production endowments of either I_R or I'_R . Considering the two alternative endowments I_N and I_R , the price vector is given, in both cases, by the tangent to the *PPF* at E . In figure 1 the post-trade distribution of goods is shown for both N and R rules. Q_N and Q_R represent the Pareto optimal allocation of total product for N and R rules, respectively.

Under the above conditions the Pareto optimality of competitive equilibria is independent of ownership. When differential wealth effects are entered into the analysis, the difference in resource endowments will induce income effects which alter the aggregate demands for the two commodities. In this case the production equilibrium for the R rule may be different from point E , the production equilibrium for the N rule. Relative prices will be altered and new welfare positions will be attained. The equilibrium will, nonetheless, be Pareto optimal. Both N and R rules permit trade in the interdependence level, thereby correcting the externality within this highly simplified model.

To summarize, the extant externality represents an irrevocable interdependence among economic agents. If we begin with a situation resembling the N rule, then instituting an R rule constitutes a "reversal" of the active property right. N and R rules, both being acts of internalization through market creation, are beset by the same technical interdependencies among economic actors. Therefore, ownership reversal cannot bring about Pareto improvements in production or utility possibilities. Reversal may easily cause movements along *PPF*'s or *GUPF*'s, but outward shifts in these frontiers will not be possible. The effects of transaction costs represent a major caveat to this rule, a fact to be discussed shortly. For now, we state with confidence the following Coasian postulate.

POSTULATE 1. *Ownership reversal can never improve upon production or utility possibility frontiers in a world without transaction costs.*

Transaction Costs and Social Optimality

It is a trivial extension of presently accepted doctrine to expand the above model into the world

³ At one time N and R rules have been termed L and \bar{L} laws (Mishan), and L' and \bar{L}' are similarly defined "liability rules."

of nonzero transaction costs as follows. *N* and *R* rules differ, in general, with respect to both the total amount of transaction costs that these rules impose and the distribution of these costs. Differences in the distribution of these costs will interact with wealth effects and budget limitations to produce further differences in the resulting competitive equilibria. Distributional issues aside (momentarily), any positive amount of transaction costs will prevent otherwise advantageous transactions from occurring. At this point it becomes appealing to argue that transaction costs prevent competitive equilibria from achieving Pareto optimality. We do not, however, succumb to this temptation.

Transaction costs are real and unavoidable aspects of any economic system. It is not even possible to eliminate transaction costs by prohibiting all trade because such a decree would have to be deliberated and enforced and other institutions would emerge to replace banned markets. The inevitability of transaction costs means that any notion of Pareto optimality is incomplete until transaction costs are incorporated. In what follows we shall set about this task by inquiring how welfare frontiers such as the *PPF* and the *GUPF* are affected by the adoption of either *N* or *R* rules together with their implicit transaction costs.

At the beginning it is crucial to observe a few fundamental points regarding the interdependence which constitutes the general externality to which the *N* and *R* rules are directed. First, the interdependence is produced; it is not an inherent part of the environment but is the result of particular production and/or consumption activities undertaken by man. Second, the production of this interdependence is functionally related to one, several, or many different variables controllable by man. Third, the precise nature of this functional relation may be uncertain; indeed, some of the determining variables may be unknown. Fourth, it is costly to monitor both the interdependence level and its known determinants.

Incorporating Transaction Costs

Let us begin to introduce the effects of transaction costs through example. In the pursuit of killing weeds on my farm, I ameliorate a detrimental externality that I have been perpetrating upon neighboring farmers through the propagation of weed seed. My neighbors derive external benefit from my weed control activities

as I do from similar actions taken by them. The reciprocity of this relationship does not mitigate the externality. I tolerate or take action against my weeds as I see fit, regardless of the actions taken by my neighbors. Each person's neighbors have the duty to receive weed seeds.

Let us contemplate an alternative ownership pattern, an *R* rule, in which my neighbors have an enforceable right to be free of the nuisance induced by my weeds. A pure *R* rule would assign me the duty to manage my farm in such a way as to prohibit the germination of "my" weed seed on any farm but my own. Otherwise, it will be necessary for me to purchase an appropriate amount of weed-seed-propagation rights for my farm—rights which are initially held by the neighbors under the *R* rule.

The terms of the *N* and *R* rules suggested in this example represent technically perfect statements of opposing property rights. On the one hand, I am free to allow my weed seed to germinate on others' land. Under the opposite rule, I must prohibit any weed seed from leaving my property and then germinating. The "perfection" of these rules lies in the fact that the alternative property rights are stated in terms of the actual interdependence, i.e., the amount of weed seed leaving my farm and sprouting on neighbors' farms.

Statement of property rules in any other terms would be technically imperfect. An obvious example would be if an *R* rule prevented me from having weeds on my farm without trading for the rights held by my neighbors. In this case, if I do not purchase rights to have weeds on my farm, then I must eliminate all weeds. No other method of controlling the spread and germination of weed seed is admitted. Clearly, the propagation of weed seed is related to the amount of weeds, but the relationship is not complete. For example, if I trim my weeds frequently, the propagation of seed will be minimal. I could chemically retard the formation of seed without killing the weeds. Or, at the extreme, my weeds may be of a hybrid, infertile variety. A property rule which is stated in terms of a surrogate measure instead of the actual interdependence will not recognize these and other possibilities. This situation applies to all externalities but to differing degrees.

Establishing a workable *R* rule favoring one's neighbors in the weed seed scenario requires that an index/measure be formulated. At least four alternatives exist for an *R* rule favoring one's neighbors. We could state that each landowner (a) may not allow his/her weed seed to ger-

minate on others' land, (b) may not allow his/her weed seed to move to others' land, (c) may not possess reproducing weeds, or (d) may not grow any weeds. Trade can occur following the adoption of any of these *R* rules, but only option (a) embraces the actual interdependence. Options (b)–(d) employ surrogates for the interdependence and therefore embody misconceptions regarding the interdependence. This is a problem of transaction costs because surrogates are otherwise unnecessary.

The essential point is that technically imperfect property rules do not recognize, by definition, certain externality control processes. If the property rule ignores a control mechanism which would have been employed under costless information, then the rule results in a *PPF* and/or a *GUPF* which is interior to the idealistic frontiers which ignored transaction costs. In a world devoid of transaction costs, imperfect formulations of property rules will be unimportant to efficiency. Without transaction costs, information shall be perfectly and universally available to all. Actual interdependence levels will be perfectly and costlessly monitorable, and precise relationships between externality generation and externality determinants will be known. In the absence of such idealistic conditions we have:

POSTULATE 2. If a particular property rule is technically imperfect, then the PPF and GUPF will be shifted inwards even though transaction costs are otherwise zero.

According to postulate 2, the effects of an imperfect property rule for externality "correction" cannot be fully overridden, and this restrains production and/or utility possibilities. While market activity with an imperfect rule presumably will bring about some mutually beneficial transactions, some beneficial transactions will be avoided and some bad transactions will occur because of incorrect judgments regarding the nature of interdependencies.

On the other hand, use of surrogate measures in property rules is a justifiable response to transaction costs. A technically perfect property rule can be informationally demanding in practice and thereby incur high transaction costs. Of the four identified options for defining a weed seed *R* rule, only option (a) is technically perfect. It is also economically onerous, for it is difficult to imagine the costliness of a monitoring network capable of tracking the origin, transport, and growth of weed seeds. Clearly, an economically rational response to transaction

costs may be to select interdependence surrogates for property rule formulation. Why else would we buy and sell oranges by the pound when we truly desire juice and pulp of good quality (Barzel)? Why do western water rights specify acre-feet diverted rather than consumed? How closely does tons per acre per year really represent complex soil erosion interdependencies? Surrogate measures of externality interdependencies are important, and postulate 2 is therefore relevant.

The arguments presented thus far have not addressed the nature of the respective welfare frontiers for *N* and *R* rules that utilize equivalent indices. While transaction costs can exhibit some similarities for opposing *N* and *R* rules employing the same index, the effect is likely to be unique. The following postulate offers one reason.

POSTULATE 3. Transaction costs increase with the distance between initial endowments and final (post-trade) allocations.

The most important implication of this postulate is that transaction costs convey inertia to initially erected property rights. Because market participants are reluctant to incur transaction costs, the restraint to trade caused by the existence of transaction costs implies that post-trade allocations of rights will bear some resemblance to initial endowments.⁴ The extent of the resemblance depends on both the magnitude and distribution of transaction costs: greater transaction costs giving rise to a greater resemblance between pre-trade and post-trade allocations. The distribution of these costs is also pertinent. For example, to the degree that transaction costs are borne by individuals (or entities) who are not directly involved in the interdependence (e.g., a government authority), the inertia of initial endowments will be lessened.

Once a particular property rule and the mechanism for enforcing this rule are adopted, the amount and distribution of transaction costs are more clearly assigned (though still unknown). That is to say, the burden of information generation is more apparent. As a consequence of adopting a specific rule, traditional production and utility possibility frontiers must be shifted inward to reflect the amount of resources which are consumed for the production of information

⁴Randall (1983) has observed this consequence of transaction costs and has also stated that the income effects of alternate property rules cause similar differences in post-trade allocations.

and lost because of imperfect decisions made under imperfect information. That is, the traditional concepts of *PPF* and *GUPF* do not incorporate the very real costs imposed by transaction costs. Once property institutions are known, adjustments to welfare frontiers within our theoretical constructs can and should be performed to account for these costs.

POSTULATE 4. *Once transaction costs are admitted, different property rules give rise to different welfare frontiers.*

In figure 4 the *PPF* relating to a hypothetical *R* rule is drawn as the locus *PPF_R* which lies strictly interior to the original, idealistic frontier. For generality *PPF_R* lies strictly interior to the old frontier to indicate that information generation will occur even in the absence of transactions. Transaction costs incurred by the public sector would also be incorporated in determining *PPF_R*. Property right inertia due to the inherent transaction costs of the *R* rule implies a proportionately greater inward shift along the lower end of the *PPF* (assuming that the *R* rule was imposed for a detrimental externality).

Similarly, *PPF_N* represents production possibilities for the *N* rule. Presumably, inertia under the *N* rule will favor greater production possibilities for *X* in comparison to the *R* rule. Under the *R* rule, larger amounts of bargaining and monitoring activities must be pursued in order to have a larger production of *X*, that is, a greater number of rights must be exchanged.

Each of these production frontiers relates to a specific *GUPF* which also incorporates trans-

action costs. It is not, however, true that intersecting production possibility frontiers produce intersecting grand utility possibility frontiers. It is therefore feasible for either *GUPF_R* or *GUPF_N* to be everywhere superior.

Regardless of the relative positions of the two pairs of welfare frontiers, we might impose social indifference curves of the form

$$W = W(U_{\alpha}, U_{\beta})$$

on the alternative *GUPF*'s, as in figure 5, in order to determine whether the *N* or *R* rule is socially preferred. Equivalently, as in figure 6, welfare indifference curves of the Bergson variety,

$$B = B(\$, X),$$

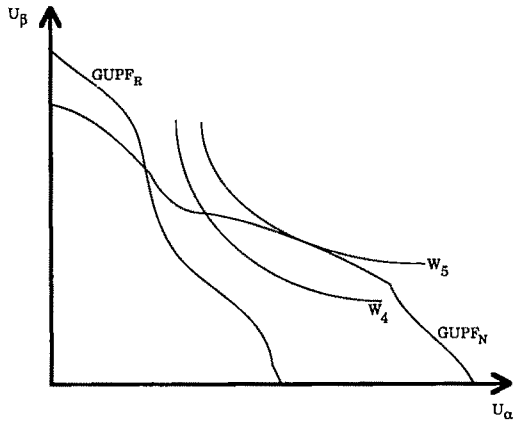

Figure 5. Social optimization in utility space

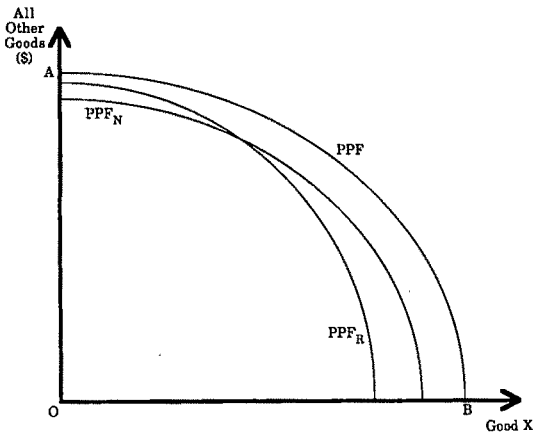

Figure 4. Production possibilities for alternative endowments with transaction costs

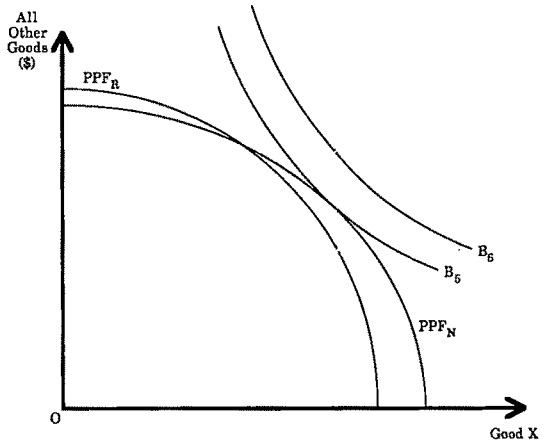

Figure 6. Social optimization in goods space

could be drawn together with the two alternative *PPF*'s to illustrate the socially optimal property rule. Either approach is flawed.

Choice between Opposing Property Rules

While the imposition of social indifference curves is a nice theoretical device for illustrating the "optimal" choice of property rule with transaction costs, it is neither realistic nor helpful. Beyond the obvious acknowledgement that we do not possess a social welfare function, these devices treat every point on the welfare frontiers as being attainable even though each frontier corresponds to a particular distribution of the property rule in question.

The welfare frontiers in effect for the two distinct property rules can become determinant only by incorporating the burden of information costs. This, in turn, requires distribution of the property right under examination. However, this same fixity tends to define the resulting competitive equilibrium by declaring an initial endowment. Each such endowment will presumably support a unique competitive equilibrium which is represented by a single point on the appropriate welfare frontier.⁵ Because true welfare frontiers must incorporate transaction costs and because the inclusion of transaction costs requires property right specification which then fixes the competitive equilibrium, the concepts of Pareto optimality and competitive equilibrium appear to come perilously close to being definitionally identical. Randall (1983) has employed this closeness to argue that "externality" and "Pareto relevance" are vacuous terms. This argument is feasible only when nonmarket institutions are assumed inferior and no Pareto-inefficient definitions of property rights are envisioned.

Focusing now on the correct interpretation of the choice between polar *N* and *R* rules, it is clear that the two alternatives present distinct welfare frontiers. Furthermore, only one point

on each of these frontiers, the competitive equilibrium, is relevant to the decision. In figures 7 and 8 the diagrammatic illustration of a newly emerged production externality is continued.⁶ Regardless of whether the new interdependence is positive or negative, the *N* rule favors the producers of the externality, in this case the producers of *X*. As depicted in figure 7, the *N* rule results in an initial endowment given by I_N , an output vector given by F , and an output distribution of Q_N . The determination of these three points is simultaneous; even I_N is dependent on F since I_N represents post-production claims on net output.⁷ Because property right inertia brought on by transaction costs will favor greater *X* production under an *N* rule than an *R* rule, point F lies to the left of point G . Post-production endowments and output distribution are similarly depicted for the *R* rule.

Contract curves OF and OG in figure 7 define utility possibility frontiers in utility space where α and β are the groups of completely homoge-

⁶Production-consumption and pure consumption externalities can also be illustrated in this framework. Where production activities have externality impacts on utility functions, indifference mappings (and contract curves and utility possibility frontiers) will depend on equilibrium production. Where production opportunities are affected by consumption activities, production possibility frontiers will be jointly interrelated to actual consumption. Nonmarket interrelationships between consumers will likewise shift indifference maps and utility possibility frontiers. In all of these situations *N* and *R* rules will necessarily induce disparate utility possibility frontiers. Moreover, since wealth effects may generally occur and transaction costs may vary, different production possibility frontiers may result from *N* and *R* rules.

⁷As demonstrated with figure 1, the placement of I_N is rather arbitrary. Its exact location is not important for the purposes of the present discussion.

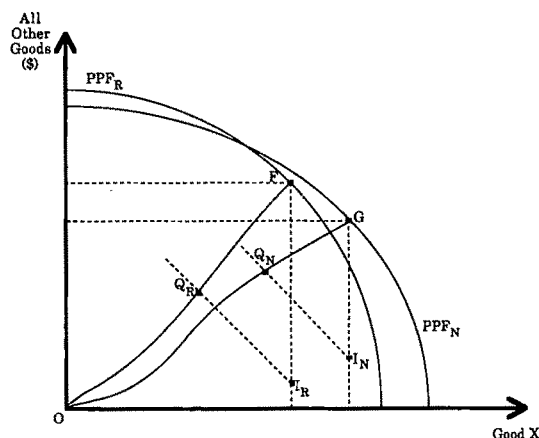

Figure 7. Equilibria for alternative endowments with transaction costs

⁵Lump-sum transfers of other resources could be mistakenly viewed as making viable equilibria out of other points along $GUPF_N$ or $GUPF_R$. This is an oversimplification that underestimates the difficulty with which redistributive policy is performed. It is one thing to design an externality-addressing property rule of the sort under discussion here and quite another to pair such a rule with an unspecified redistributive policy. Such a policy would be accompanied by its own unique burden of transaction costs. In the face of these costs neither $GUPF_N$ nor $GUPF_R$ is relevant. Another frontier recognizing the particulars of the chosen transfer policy is needed. Each property rule or each pairing of a property rule and a lump-sum transfer policy will be associated with a unique *UPF*. Subsequent action by individuals will lead to a point on this frontier.

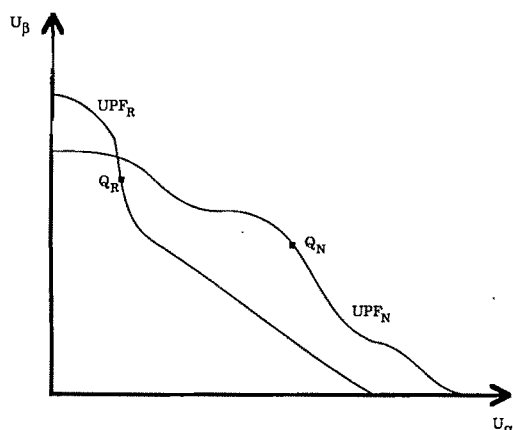

Figure 8. Equilibria with transaction costs in utility space

nous X -producers and all others, respectively.⁸ These welfare frontiers are illustrated in figure 8 as are the equilibrium utility levels resulting from human action within the whole system of preferences, technology, and institutions. Points Q_R and Q_N completely summarize the welfare implications of property right choice. There are no conditions to prevent one of these equilibria from lying within the frontier defined by the other property right (as depicted in fig. 8). Nor is this relevant. The choice between property rules is a choice between the equilibrium outcomes rather than between the frontiers on which the outcomes lie. Each welfare frontier is not completely feasible. Economic activity cannot lead to an arbitrary point of the frontier.

POSTULATE 5. *The incorporation of transaction costs required for realistic welfare frontiers has the side effect of rendering irrelevant all but one point on the welfare frontier. The choice between opposing N and R rules is a choice between two and only two economic states.*

Therefore, the choice between N and R rules is reduced to a choice between Q_N and Q_R . The welfare frontiers are inconsequential, and the only choice involves whether group α or β is to be favored. Moreover, the choice itself is likely dominated by pre-existing social institutions constituting the fabric of mutual coercion. In specific instances these institutions may rigidly dictate which property rule (and which group)

is to be ascendant. Of course, to the extent that flexibility in property right choice remains, we can expect each group to exploit its noneconomic opportunities for property right capture.⁹

Because of these facts, it is rarely possible for economists to interpret property rule reversals as economically inefficient. Regardless of the relative positions of welfare frontiers, the alternative economic outcomes will be Pareto non-comparable as in figure 8. Only in rare cases where Q_N is preferred to Q_R (or vice versa) by both α and β can a clear position be taken.

Institutional Choice

By utilizing two different applications of the same institution, the preceding discussion has demonstrated the dependence of economic efficiency on institutional choice. Were it not for transaction costs, postulate 1 would apply, and Pareto optimality would be divorced from the selection of institution. It should be noted that the Pareto optimality of competitive equilibria has not been investigated here (as in the Coase theorem) but has been taken for granted. Previous sections have considered the ramifications of incorporating transaction costs into the determination of Pareto optimality. By making transaction costs endogenous, the choice between N and R rules becomes a choice between two different economic states, both being Pareto optimal. Production and utility possibility frontiers are irrelevant because they are infeasible. Each of these property rules is capable of supporting a single Pareto optimum.

It is now appropriate to enrich this analysis with a consideration of internalizing institutions other than N and R property rules. Many such institutions are important, but an exhaustive listing of these would be tedious. Even so, considerable insight can be achieved by inspecting some of the more noteworthy alternatives. First among these is the multitude of property rules lying along the spectrum whose endpoints are defined by N and R rules.

Other Property Rules

Between the two extremes represented by N and R rules, there is a large, indeed infinite, number

⁸The presumed uniqueness of the competitive equilibrium implies that only one point on the production possibility frontier (and, therefore, only one contract curve) is relevant. Thus, a single utility possibility frontier, not the grand utility possibility frontier, is the appropriate concept relating to a specific property rule.

⁹As Bromley has observed, it is the incidence of gains rather than the opportunity to obtain net social gains that motivates institutional change (1989, p. 240).

of alternative property rule specifications. These choices differ with respect to the endowed level of interdependence that instigators can/must generate and, simultaneously, the endowed level of interdependence that receptors must tolerate/enjoy. Expanding upon Bromley (1989), it could be said that we are now exploring alternate linear combinations of rights and duties. For example, property rules could vest farmers with (a) the right to grow 100 weeds per acre and the duty not to exceed this amount, (b) the right to generate two tons of soil loss per acre per year and the duty not to lose more soil than this, (c) the duty to produce 200 pounds of oranges each year and the right to output in excess of this amount, etc. Transfer of these endowments is allowed and is the basis of market activity. In the case of the typical marketed commodity, manufacturers are empowered to produce and withhold the commodity. Potential consumers must tolerate this authority unless they purchase a portion of these rights.

In the case of a positive externality a property rule can be adopted which forces each instigator to produce y units of the interdependence. At the same time such a rule will specify the initial allocation of these y units (assuming rivalness) among the interdependence benefactors. The quantity y can be any positive number, thereby illustrating the infinite possibilities for alternative property rules. Clearly, if y is identically zero, then we have an N rule. As y gets large, the property right trends towards becoming an R rule. This indicates an area where the earlier discussion was not definitive. In the case of a beneficial interdependence the magnitude of y needed to erect an R rule is ambiguous.¹⁰

Consideration of property rights which are intermediate to N and R rules or which employ alternative surrogate indices for the true interdependence simply generalizes earlier discussion. Some of the more important conclusions bear restatement under these more general conditions.

- Each alternative property rule will exact its own unique magnitude and distribution of transaction costs. In each case ensuing transactions will be vectored by the current information base regarding known and economically measurable determinants of the externality interdependence.
- Property rule inertia induced by transaction

costs will favor the initial distribution. In this way different property rules imply different distributions of attainable economic welfare.

- Each distinct property rule will be associated with a single attainable point in utility space (postulate 4). In general, many of these points will be Pareto noncomparable.

Using the same techniques employed to obtain figures 7 and 8, the attainable levels of welfare associated with alternative property rules can be shown in utility space. The outer limit of these points depicts the choices inherent to the choice among alternative property rules (fig. 9). This locus (possibly discontinuous) might be termed the Property Rule UPF . When property rules represent the only institutional variant for addressing an externality relationship, this frontier fully depicts the scope and implications of institutional choice. Every point on this frontier is attainable in the sense that actual transaction costs are endogenous.

The welfare frontier depicted in figure 9 must not be confused with the traditional concepts of UPF 's or $GUPF$'s. UPF 's are utility space mappings of contract curves, and a $GUPF$ is the outer limit of an infinite number of UPF 's (one for each point on the PPF). The property rule UPF in figure 9 is composed of single points from a particular class of UPF 's incorporating transaction costs. The Property Rule UPF is not an outer limit of these UPF 's, but it is the outer limit of competitive equilibria lying on the UPF 's. The property rule for a single externality interdependence is variant along the welfare frontier depicted in figure 9; all other institutions are fixed. Social constraints which might narrow the feasible set of property rules for this

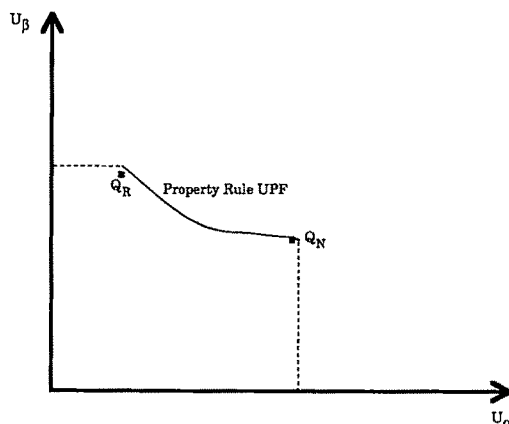

Figure 9. Property rule utility possibility frontier

¹⁰Similarly, in the case of a detrimental externality y would denote the amount of the interdependence that instigators are allowed to produce. Under these conditions $y = 0$ implies an R rule, and the size of y necessary to achieve a pure N rule is indeterminate.

interdependence have been disregarded in the construction of this frontier.

Liability Rules

The welfare frontier originating from the preceding discussion lays the basis for similar analysis involving broader dimensions of institutional choice. Certainly, the analysis should be extended to include liability rules. It has been demonstrated that liability rules differ dynamically from property rules (Buchanan and Faith, Frech). The static nature of the economic tools being employed here prevents immediate attention to these dynamic elements. There appears to be little opportunity to usefully depict the effects of today's institutions on tomorrow's welfare frontiers except by adding a time dimension to the welfare frontiers, and this extension is not pursued here.

Liability rules also differ from property rules in terms of transaction costs and the degree of afforded protection. Liability rules offer less protection to endowed individuals than do property rules. Therefore, the liability rule possesses less market value. Transaction costs are distributed quite differently when comparing liability rules to property rules (Bromley 1978), and, since the *ex post* determination of value in the case of liability rules requires an expensive judicial system, a large portion of transaction costs are borne by third parties. Like property rules, alternative surrogates are available and liability rules are continuously assignable, and, therefore, a Liability Rule *UPF* similar to that in figure 9 is presumably applicable.

Government Externality Policy

The final major category of externality-addressing institutions to be separately considered here pertains to various forms of government policy. Types of government policy traditionally discussed by economists include quantity-guided controls such as prohibition, standards, and regulation in general, as well as price-guided controls such as taxes, charges, subsidies, cost-sharing, and various other economic incentives. Perhaps the only characteristic serving to unify this class of institutions is that they are all modes of nonmarket activity. However, economic incentives are usually characterized as decentralized while regulation is quite centralized (Schultze), and a great deal of literature is devoted to contrasting these two subgroups.

Like the variety of property institutions which address externality interrelationships, the purpose of these alternative forms of nonmarket activity is to assist in establishing social and economic structure. The use of surrogate measures is also relevant. Market and nonmarket institutions are quite similar in that neither avoids transaction costs and in that reversal is a relevant approach for contrasting polar images of the same institution. For example, in the case of beneficial externality, a regulation can conceivably state that a producer of the externality need not produce the interdependence at any level or, alternatively, that a producer must produce y units of the interdependence. Because these are regulations, trade in these units between instigators and receptors is not possible in either case. If the externality takes on aspects of a rival good in that its use is consumptive, then the regulation might also state a distribution of these y units among recipients.

In this way, transaction costs pertaining to the direct relationships between instigators and receptors are greatly lessened. Instead, transaction costs are incurred via the relationships between instigators and government, on the one hand, and between government and receptors on the other. As with market exchange processes, transaction costs can be quite substantial, and polar regulations or polar incentives will differ greatly in the magnitude and distribution of transaction costs. Because of the existence of transaction costs, perfect enforcement of regulations is not attractive, and, depending on the magnitude of administrative transaction costs, resulting economic activity will stray from promulgated regulations. Still, as is the case with property rules, resulting economic activity will bear some resemblance to established regulations and will be sensitive to regulatory choice.

It must therefore be clear that alternative forms of government policy or alternative specifications of the same policy will relate to different levels of attainable welfare. Technology is unaffected by available policies in this static setting; but, once a policy is chosen, transaction costs influence the outcomes which result in attained welfare. Again, if the concept of economic efficiency truly relates to attainable levels of welfare, then the concept cannot be independent of policy alternatives. Different policy actions induce different levels and distributions of transaction costs, and it is not accurate to say that one particular policy is economically efficient without accounting for these differences.

It comes as no surprise at this point that each nonmarket (policy) alternative is to be associ-

ated with a single economic outcome in terms of production, consumption, and utility levels. This outcome is selected by the whole of individual and collective action from transaction-cost-endogeneous welfare frontiers. Moreover, the results of many of these policies will not be Pareto comparable, and the locus of outermost production or utility levels can be used as an efficiency frontier for nonmarket action.

Institutional Welfare Frontiers

Because Pareto optimality cannot be divorced from institutional alternatives for a given externality, any welfare frontier depicting the range of efficient economic states must consider a variety of institutions. Institutional alternatives are endogenous to the construction of true welfare frontiers. It is evident at this point that the revised construction of welfare frontiers, elucidated earlier in the context of variable property rules, can be readily expanded to incorporate a much broader range of institutions.

Implementation of different property rules, liability rules, regulation, incentives, customs and behavioral standards, and other nonmarket devices are construed as separate institutions with distinct economic consequences. The inherent transaction costs of each specification of each institution will produce an institutionally specific production possibility frontier and utility possibility frontier, but individual action within the system of constraints and incentives will succeed in isolating a single point on each of these frontiers. Other points on these frontiers are not feasible (in the sense that they will not be chosen) and, therefore, are not entertainable as efficient. Various economic states then correspond to various institutions. Where these states are Pareto comparable, specific choices can be identified as inefficient. Minimally, there are property rule, liability rule, and nonmarket UPFs applicable for each externality. Superimposing these welfare frontiers and forming the outer limit to eliminate all inefficient alternatives will reduce the institutional choice set to a Pareto non-comparable group. This group is representable by a curve or surface in utility space which shall be called the Institutional UPF (*IUPF*) (not illustrated). The modifier "grand" is unnecessary here, but the frontier is, indeed, grand in the sense that it embodies the full spectrum of internalizing actions available for a given interdependence. All forms of ownership, protection, nonmarket policy, and, in general, all aspects of mutual coercion are endogenous to

the *IUPF*. Grand utility possibility frontiers of earlier literature only incorporated resource and technological constraints. The *IUPF* also accounts for the range of humanly imposed constraints available to order human interaction.

An institutional *PPF* can also be illustrated in output space; each point on this efficiency locus corresponds directly with a point on the *IUPF* and a particular institutional specification. However, the *IUPF* is generally a more fundamental and interesting concept because it highlights resultant utility levels. While variable institution welfare frontiers definitely connote abstract concepts, they are no more abstract than traditional welfare diagrammatics and are far more useful as a paradigm for institutional choice.

Implications for Portraying Institutional Choice

Within the framework provided by variable institution welfare frontiers, shifts in property assignments and nonmarket policies are best depicted as movements within the region bounded by the *IUPF*. This pertains to the choice of new or different institutions as well as incremental changes in a certain type of institution. Pareto-relevant externalities are properly characterized as interdependencies currently being addressed by market/nonmarket structures associated with economic states that are strictly interior to the *IUPF*. Pareto-irrelevant externalities are those relationships being accommodated by institutions which place the economy on the *IUPF*.

One approach to "remedying" an externality is judged to be better than another on the basis of the Pareto criterion, and, in this way, the *IUPF* leads to an institutionally unbiased comparison of alternative choices. The potential usefulness of variable institution welfare frontiers as a theoretical concept stems from this unbiasedness. In practice, it is unacceptable to define externality as an "interdependence without a market." An externality is merely an interdependence. If an externality is Pareto-relevant (we are not on the *IUPF*), then some sort of policy is needed, but that policy is not necessarily a market.

Most important, these frontiers are not idealistic in that an unachievable norm for efficiency is maintained. Variable transaction costs and the effects of these transaction costs are endogenous. Social action for externality amelioration is therefore justified if current institutions do not place the economy on the *IUPF* or if current institutions do place the economy on this fron-

tier but with undesirable distributional consequences.

One purpose of this theory is to give explicit recognition to the fact that externalities do not emerge into institutional voids but are always being addressed by some, perhaps very subtle, coercive structure. In this sense externality correction, resolution, and internalization are all vague terms unless they refer to institutions which, if adopted, would move society to the *IUPF*. Because a proper analysis incorporating transaction costs has never been performed to investigate the global efficiency of a prospective institution, the applicability of such terms is highly questionable in all but conceptual work. Moreover, the empirical difficulties to be encountered in such a rich analysis imply that the chances of ever satisfying this requirement are quite remote.

Finally, it is impossible to appeal to economic efficiency (in the Paretian sense) as a norm to guide institutional choice. Taking the *IUPF* and dimensioning it into hyperspace to accommodate a utility axis for every individual has the effect of grossly multiplying the number of Pareto noncomparable (and therefore efficient) institutions. The economic analysis of social options intended to accommodate a given externality interdependence will rarely be able to consider a wide range of alternatives. Agenda formation within decision-making and research processes almost certainly excludes many institutional alternatives because of the limited scope of these processes and our limited abilities to understand and characterize many alternatives. Institutional bias may always be present because selection is from a subset of the actually available institutions.

Factor Demands in the U.S. Food-Manufacturing Industry

Kuo S. Huang

This paper analyzes the demand for labor, capital, and energy in the U.S. food-manufacturing industry using Allen and Morishima elasticities of substitution. The demand for capital is more elastic than for labor and energy, and these production factors are substitutable, especially between capital and labor.

Key words: conditional factor demands, elasticity of substitution.

Some U.S. food-processing technologies require heavy use of energy and capital equipment, while labor costs relative to value of shipments are smaller than for other types of manufacturing. In past years, the food manufacturers faced a steady increase in the price ratio between labor and capital and a sharp increase in the price of fuel and energy during the 1970s but a continued decrease since 1981. To make decisions in resource allocation, food manufacturers need information on the nature of industrial demand for factor inputs.

Numerous studies have analyzed demand for production factors in various sectors of an economy. Examples include Berndt and Christensen, Berndt and Wood, and Fuss in the general manufacturing sector, and Binswanger, Ray, Lopez, and Shoemaker in the agricultural sector. However, little attention has been given to factor demands in the U.S. food-manufacturing industry. The objective of this study is to analyze the demand for nonfood inputs such as labor, capital, and energy in U.S. food manufacturing. Agricultural or marine raw products and packaging and containers are not considered, partly because of little perceived interdependent relationships between materials and nonfood inputs and partly because of difficulty in measuring quantity and price.

In addition to the Allen partial elasticity of substitution (*AES*), a major focus is on measuring the Morishima elasticity of substitution (*MES*) to explain factor demands and their interdependent relationships. Because *MES* is not frequently used by applied economists, a brief ex-

planation of *MES* and its linkage to cost function is given followed by an application to the U.S. food-manufacturing industry.

Conceptual Framework

Consider a production technology $F(X)$ for a vector of n -factors X . The corresponding cost function is defined as the minimum cost of attaining product Q at a vector of factor prices W as

$$(1) \quad C(W, Q) = \min_x [W'X; F(X) = Q].$$

This cost function is concave and linear homogenous in W .

Denoting $C_i(W, Q)$ and $C_{ij}(W, Q)$, respectively, as the first- and second-order partial derivatives of the cost function with respect to factor prices, one can apply Shephard's lemma and derive a conditional factor demand for the i th factor X_i^* as a function of W and Q :

$$(2) \quad X_i^*(W, Q) = C_i(W, Q).$$

This conditional factor demand function is homogenous of degree zero in factor prices. Furthermore, the (constant-output) cross-price elasticity, E_{ij} , for i th factor with respect to j th factor price is then obtained as

$$(3) \quad E_{ij} = W_j C_{ij}(W, Q) / C_i(W, Q).$$

Hicks defined the elasticity of substitution for a two-factor production function as the ratio of factors in response to a change in their relative prices. Later Allen (p. 504) extended the definition to account for the adjustments for more than two factors and defined "partial elasticity

Kuo S. Huang is an agricultural economist with the Economic Research Service, U.S. Department of Agriculture.

The author wishes to thank Lester Myers and *Journal* reviewers for helpful comments.

of substitution" between i th and j th factors as below:

$$(4) \quad AES_{ij} = \left\{ \left[\sum_{i=1}^n X_i^*(W, Q) F_i \right] / [X_i^*(W, Q) X_j^*(W, Q)] \right\} (F_{ij}^*/F),$$

where F_i is the marginal product of i th factor, F is a determinant of the Hessian matrix (its element denoted as F_{ij}) bordered by marginal products, and F_{ij}^* is a determinant of the cofactor of F_{ij} in the matrix of F .

Although AES has been widely used, its applicability to the demand for production factors is rather limited. The definition of AES deviates from Hicks' definition for two-factor production and does not explain factor substitution explicitly. Besides, AES is not a measure of the curvature of the isoquant, it provides no information about relative factor shares, and it cannot be interpreted as the marginal rate of substitution (Blackorby and Russell).

An alternative measure of factor substitution known as the Morishima elasticity of substitution is defined as a logarithmic derivative of a quantity ratio in factors with respect to a ratio of its factor prices:

$$(5) \quad MES_{ij} = -\partial \ln[X_i^*(W, Q)/X_j^*(W, Q)] / \partial \ln[W_i/W_j].$$

MES measures the percentage change in the ratio of a pair of factors in response to a change in their relative prices. It is a natural generalization of the Hicksian two-variable elasticity.

Because the conditional factor demand function (2) is homogenous of degree zero in factor prices, the demand function is invariant by dividing through the prices with a particular price, say W_j ; that is,

$$(6) \quad X_i^*(W, Q) = X_i(W_1/W_j, \dots, W_{j-1}/W_j, W_{j+1}/W_j, \dots, W_n/W_j, Q).$$

The differentiation can be carried through the chain rule by differentiating the $X_i(\cdot)$ directly with respect to the variable expressed in terms of W_i/W_j . The result is a workable form of MES expressed as

$$(7) \quad MES_{ij} = E_{ji} - E_{ii}.$$

This derivation is more convenient and straightforward than the expression derived in Blackorby and Russell.

According to equation (7), the effect of a variation in the factor price ratio W_i/W_j can be divided into two components: (a) the effect on $X_j^*(W, Q)$ given by the cross-price elasticity E_{ji} , and (b) the effect on $X_i^*(W, Q)$ given by E_{ii} . One property of MES is asymmetry in that the effects of change in W_i/W_j and W_j/W_i upon their corresponding adjustments to the ratio of factor demands need not be the same. MES can also provide complete comparative static information about relative factor cost shares in response to a change in factor prices expressed as

$$(8) \quad \frac{\partial \ln[W_i X_i^*(W, Q)/W_j X_j^*(W, Q)]}{\partial \ln[W_i/W_j]} = 1 - MES_{ij}.$$

The relative cost share is decreasing (increasing) if the MES is greater (less) than one.

Thus far, factor demand relationships are expressed in terms of an unknown cost function. Some empirical applications use a translog cost function expressed as

$$(9) \quad \ln C = \sum_{i=1}^n \alpha_i \ln W_i + 1/2 \sum_{i=1}^n \sum_{j=1}^n \beta_{ij} \ln W_i \ln W_j + \sum_{i=1}^n \beta_{iq} \ln Q \ln W_i + \alpha_q \ln Q + 1/2 \beta_{qq} (\ln Q)^2 + \sum_{i=1}^n \delta_i \ln W_i T + \delta_q \ln QT + \mu_1 T + \mu_2 T^2,$$

where variables C is cost, Q is production, W_i is the i th factor price, and T is a time trend to represent the level of technical progress.

To ease potential estimation problems such as lack of degrees of freedom, the cost function is not estimated directly; rather, a set of the factor cost share equations is estimated. A typical cost share equation for i th factor, say S_i , derived by applying Shephard's lemma to the cost function is expressed as

$$(10) \quad S_i = \alpha_i + \sum_{j=1}^n \beta_{ij} \ln W_j + \beta_{iq} \ln Q + \delta_i T \quad i = 1, 2, \dots, n.$$

Moreover, in order to satisfy the properties of neoclassical production theory and the adding-up property of cost shares, the following parameter restrictions are required:

$$\sum_{i=1}^n \alpha_i = 1, \beta_{ij} = \beta_{ji} (i, j = 1, 2, \dots, n), \text{ and} \\ \sum_{j=1}^n \beta_{ij} = \sum_{i=1}^n \beta_{ij} = \sum_{i=1}^n \beta_{iq} = \sum_{i=1}^n \delta_i = 0.$$

Given the estimated cost parameters, one can derive *MES*, *AES*, and the price elasticities of conditional factor demands as follows:

$$(11) \quad MES_{ij} = (\beta_{ij} + S_i S_j) / S_j \\ - (\beta_{ii} + S_i^2 - S_i) / S_i \quad (i \neq j),$$

$$(12) \quad AES_{ii} = (\beta_{ii} + S_i^2 - S_i) / S_i^2,$$

$$(13) \quad AES_{ij} = (\beta_{ij} + S_i S_j) / S_i S_j \quad (i \neq j),$$

$$(14) \quad E_{ii} = (\beta_{ii} + S_i^2 - S_i) / S_i, \text{ and}$$

$$(15) \quad E_{ij} = (\beta_{ij} + S_i S_j) / S_i \quad (i \neq j).$$

U.S. Food-Manufacturing Application: Data

To investigate the demand for labor, capital, and energy in the U.S. food-manufacturing industry, data are required on the unit price and total cost of each factor as well as on the value and quantity of industrial production. Most of the data are compiled from the *Annual Survey of Manufactures* (ASM), SIC code 20 (Food and Kindred Products) for 1971–86. Prior to this period, data for each sector of food manufacturing experienced serious definitional changes. The aggregate food sector includes the following nine categories: (1) meat products, (2) dairy products, (3) preserved fruits and vegetables, (4) grain mill products, (5) bakery products, (6) sugar and confectionery products, (7) fats and oils, (8) beverages, and (9) miscellaneous food and kindred products.

The value of food-manufacturing production is defined as the value of shipments adjusted for inventory changes of finished products. The aggregate price of the food-manufacturing product is defined as the Laspeyres price index for the producer price indexes of each food category (compiled from the *Producer Price Index*, PPI), using 1982 shipment values as weights. The aggregate price index is used to deflate the value of production to obtain an approximate quantity measure.

The cost of labor is the total wage payments for production workers, while unit labor price refers to the average wage payments per production worker per hour. The cost of energy is the total cost of purchased fuels and electric energy. The producer price index for fuel and power is used to represent the price of energy.

Implicit price deflators for gross fixed non-residential capital investment for structures and producers' durable equipment, compiled from

the *Survey of Current Business* (SCB), are used as an approximate price index for capital services. The cost of capital services for equipment and structures is the sum of depreciation, rental payments, and interest on the food-manufacturing net assets. Data for depreciation charges, rental payments, and the gross book value of depreciable assets are available in ASM. Because depreciation charges for 1972–76 and 1986 are not reported, this study projects them on the basis of a log-linear regression by fitting the depreciation charges (*D*) as a function of beginning-of-year structure and equipment assets (*K*) for 1977–85:

$$\ln D = -3.3195 + 1.0629 \ln K \\ (0.0292) \\ R^2 = 0.99 \\ D-W = 2.60.$$

Finally, the interest on net assets is calculated by multiplying the value of beginning-of-year assets by the Moody's Corporate Industrial Bond Rate from SCB.

Empirical Results

The cost structure of the U.S. food-manufacturing industry is characterized by estimating three cost share equations as in equation (10) for labor, capital, and energy. Because the cost shares of the three equations always sum to unity, the sum of the disturbances across these equations is zero at each observation. This implies that the covariance matrix of residuals is singular, and one of the cost share equations should be dropped from direct estimation. The remaining equations are then estimated simultaneously by applying Zeller's seemingly unrelated regression method, while the parametric constraints are incorporated.

As indicated in Berndt and Savin (p. 942), if one uses the covariance matrix of residuals obtained from applying ordinary least squares to unrestricted equations as prior information for estimation, the estimates of the parameters are the same regardless of which cost share equation is deleted. This study uses this approach, and the invariant property of estimates has been verified.

A time-trend variable as a proxy for technical progress was initially included in the model. However, because of multicollinearity, the estimated coefficients for the time trend were not statistically significant. Consequently, the time-trend variable was excluded from the model. In

addition, the relatively short sample period (15 years) precluded testing for structure changes in the food-manufacturing industry.

The estimation results are reported in table 1. Most of the estimated parameters (13 out of 15) are statistically significant at the 5% level. The percentages of root-mean-square error to sample mean are about 7% or less for each equation. These estimated parameters and their covariance matrix of errors together with the observed factor cost shares at sample means are the basic information for computing the estimates of factor demand relationships contained in tables 2 and 3. The factor cost shares used in the calculation are labor (0.5376), capital (0.3393), and energy (0.1231).

Based on equations (14) and (15), the (constant-output) price elasticities of factor demands

are obtained and shown in table 2. The results suggest that the demand for capital is quite elastic with an elasticity of 2.08, while the demand elasticities of labor and energy are 1.05 and 0.49, respectively. The high elasticity of demand for capital probably reflects the industry's high capital-intensive technologies. As indicated in Connor and others (p. 39), food processing is more capital intensive than such heavy industries as machinery and transportation equipment; only four major industry groups (paper, chemicals, petroleum, and primary metals) are more capital intensive than food manufacturing. The cross-price elasticities show a strong substitution relationship between capital and labor with elasticities 1.78 for the demand of capital and 1.12 for the demand of labor. Capital and energy are substitutable, and labor and energy are comple-

Note: Elasticities and their standard errors (in parentheses) are computed on the basis of equations from (12) to (15) at sample mean of cost shares. All estimates are significant at the 5% level.

mentary; however, the cross elasticities are relatively small.

The interdependencies among labor, capital, and energy are further confirmed by the Allen elasticities of substitution shown in the lower half of table 2. The elasticities signify substitution if the sign is positive and complementarity if the sign is negative. The substitution relationship between labor and capital is supported by previous studies of manufacturing industries. For example, Berndt and Christensen found that the Allen elasticities of equipment-labor and structures-labor ranged from 1.22 to 1.79 in U.S. manufacturing for 1929–68. Fuss found that the Allen elasticity between capital and labor was about 0.8 in Canadian manufacturing for 1961–71. In another study, Berndt and Wood found that the Allen elasticity between capital and labor was about 1.01 in U.S. manufacturing for 1947–71.

The Morishima elasticities of substitution calculated on the basis of equation (11) are compiled in table 3. The entries in the off-diagonal of the table reflect the adjustments of relative factors in response to a change in the ratio of relative factor prices. Their signs are all positive, implying that any pair of factors is substitutable with each other. In particular, the elasticities of factor ratios, labor-capital and capital-labor, are large, respectively, 2.83 and 3.20. The substitution between labor and energy is inconsistent with the Allen elasticity measure mainly because of different definitions; a Morishima

elasticity is related to the adjustment of two factors, while a partial adjustment of one factor is allowed in an Allen elasticity.

Both *MES* and *AES* indicate a strong substitution relationship between capital and labor. In fact, there is a trend of more intensive use of capital but less of labor in past years especially in light of the steady increase in the price ratio between labor and capital since 1982. The capital input index (1982 = 100) increased from 67.50 in 1972 to a peak of 110.15 in 1984 and then slightly decreased thereafter. On the other hand, the labor input index declined from 106.57 in 1972 to 95.02 in 1986.

The interrelatedness of factor demands is also shown in the variation of industrial cost structure in response to a change in factor prices. Based on equation (8), the elasticities of each pairwise factor cost share with respect to their factor prices are shown in the lower half of table 3. As indicated before, these results are closely related to the magnitude of Morishima elasticities; the relative cost share decreases if the Morishima elasticity is greater than one and increases if it is less than one. For example, the -1.83 elasticity of labor-capital indicates a significant reduction in the cost share of labor to capital in response to relatively higher wages than capital price. On the other hand, the 0.58 elasticity of energy-labor indicates that a marginal increase of energy price would cause an increase of the cost share of energy relative to labor.

Table 3. Morishima Elasticities of Substitution (*MES*) and Effects of Factor Price on Cost Shares

Measure	Factor Price of		
	Labor	Capital	Energy
<i>MES</i>			
Labor		2.82905 (0.29153)	0.71874 (0.11896)
Capital	3.20354 (0.32427)		2.90370 (0.30093)
Energy	0.41890 (0.04612)	0.79338 (0.08684)	
Cost share			
Labor		-1.82905 (0.29153)	0.28126 (0.11896)
Capital	-2.20354 (0.32427)		-1.90370 (0.30093)
Energy	0.58110 (0.04612)	0.20662 (0.08684)	

Note: Elasticities and standard errors (in parentheses) are computed on the basis of equations (8) and (11) at sample mean of cost shares. All estimates are significant at the 5% level.

Concluding Comments

This study analyzes the demand for labor, capital, and energy and their interdependent relationships in the U.S. food-manufacturing industry. The results show that the demand for capital services is more highly elastic than for labor and energy. Thus, any policy measures to reduce the price of capital services, such as investment tax credits and lower interest rates, would significantly increase the demand for capital. The demand elasticities of labor, capital, and energy in response to energy price changes are relatively low. They indicate that the relatively large changes in the prices of fuel and energy experienced over the sample period did not cause much adjustment in factor utilization.

The Morishima elasticity is, in general, better than the Allen elasticity for representing the factor substitution relationship because of its capability to explicitly explain the adjustment of factor combinations in response to relative price changes. The estimated Morishima elasticities indicate that labor, capital, and energy are substitutable especially between labor and capital. This is evidenced by the recent trends in the food-manufacturing industry to substitute computers and automated machines for human operations in light of the steady increase in the labor to capital price ratio.

Government Intervention in Imperfectly Competitive Agricultural Input Markets

Steve McCorriston and Ian M. Sheldon

The frequent demands for protection by the fertilizer industry in many developed countries may have important implications for the agricultural sector. This paper provides a theoretical justification for government intervention in the fertilizer market in the form of an import tariff against foreign competitors. However, a superior policy would be for the government to counter the competitive distortion that exists in the market. An even better outcome is attained by using both policies simultaneously. Moreover, since the fertilizer industry undergoes continuous structural change, the extent to which optimal policies should vary is also investigated.

Key words: fertilizer market, government intervention, imperfect competition, structural change.

In many developed countries, the domestic fertilizer industry often demands and receives government support. The bases for these requests include aid to improve the competitiveness of domestic manufacturers, to protect the industry as it undergoes rationalization, and to counteract the aggressive export policies of foreign competitors. An example of the former is the U.S. National Gas Policy Act in use over the early 1980s which lowered the manufacturing cost of ammonia (the main feedstock of most manufactured fertilizers) by an estimated 50% (European Commission). In the case of the fertilizer industry undergoing rationalization, the Japanese government imposed a number of measures to limit or exclude imports while a restructuring of ammonia, urea, and phosphoric acid facilities were being implemented (Lancaster). The latter case has been typified by the complaints in recent years by the European fertilizer industry to the EC Commission and national governments of unfair competition from Eastern bloc exporters. Some estimates report that exports from the Eastern bloc were selling at prices 25% below West European cost levels (Agra Europe).

Despite the implications of government intervention in the fertilizer industry for farmers, agricultural economists have largely paid little attention to these issues. The aim of this paper, therefore, is to explore whether there are any theoretical justifications for government intervention in agricultural input markets. The reference point for this analysis is the recent developments in the international trade literature which suggest that there may be a normative justification for government intervention in the presence of imperfect competition.

These theoretical developments are applied to the fertilizer industry using the UK market as a case study, and values for the optimal degree of protection (tariffs) are derived. However, two further issues are explored. First, the welfare effects resulting from trade policy intervention are compared with alternative policies. Specifically, the welfare effects of antitrust legislation (as proxied by a production subsidy) which corrects the competitive distortion arising in the domestic market are estimated. A final policy consideration is the simultaneous use of tariffs and antitrust legislation. Second, the theoretical justification for intervention rests on the imperfectly competitive nature of the fertilizer industry. However, market structure is not necessarily a constant variable. For example, in the case of the UK fertilizer market, firms have exited the

The authors appreciate the comments of the anonymous *Journal* reviewers on an earlier draft of this manuscript.

industry. Consequently, even if intervention is justified, the degree of intervention likely varies as market structure changes. Therefore, the response of optimal policies to changes in the structural characteristics of the fertilizer industry is also investigated.

The paper is organized as follows. The first section outlines the rationale for government intervention in imperfectly competitive markets. The structural characteristics of the fertilizer industry in developed countries are outlined in the second section. The theoretical framework, based on Dixit (1988), is presented in sections three and four. Section five calibrates the theoretical framework to the UK fertilizer market. The extent and effects of government intervention in the fertilizer market and how such government intervention should vary in response to changes in market structure and firms' behavior are then discussed.

Rent-Shifting Trade Policy

Recent developments in the international economics literature have explored the role for government policy when markets (home and foreign) are imperfectly competitive. The rent-shifting justification for an active trade policy is characterized by the work of Brander and Spence

(1984, 1985), Krugman, Dixit (1984), and Eaton and Grossman, among others. The basis for these arguments applied to an import market can be explained diagrammatically.

Two groups of firms (home and foreign) are assumed to share the domestic market. For simplicity, their costs are assumed equal and constant. With prices initially at P_1 , the domestic firms take OQ_1 of the market, while the foreign firms account for Q_1Q_2 (see fig. 1). With a tariff, the exporters' market share falls to Q_3Q_4 , while the domestic firms expand their market share to OQ_3 . As a result of the tariff, the price has now risen to P_2 and a terms of trade effect is denoted by $P_2 - t$. Domestic producers gain following an increase in profits ($A + D$), consumers lose ($-A - B - C$) and government revenue increases ($B + E + G$). The net welfare effect is $E + G + D - C$. The essence of these strategic trade policy arguments is that, despite the potentially significant losses to consumers, the increase in the domestic firms' profits coupled with the government's receipt of tariff revenue is sufficient to outweigh the consumer surplus loss.¹ Of course, this implies that the government applies equal weight to the three interest groups; if, however, the government applied a greater weight, say, to consumers' interests, then the simple rent-shifting argument for trade policy may become less desirable.

While the tariff counteracts the trade distortion, the domestic distortion of too little output persists. Consequently, if the government enforced antitrust legislation that ensured prices equalled costs, consumer surplus would increase by $I + D + E + F + H$ and the domestic firms would lose profits equal to $-I$, giving a net change in welfare of $D + E + F + H$. Clearly, if $F + H$ is larger than $G - C$, then antitrust legislation is a superior means of increasing national welfare compared to the optimal tariff. However, a first-best policy may be a combination of the tariff and antitrust legislation that counters both distortions simultaneously.

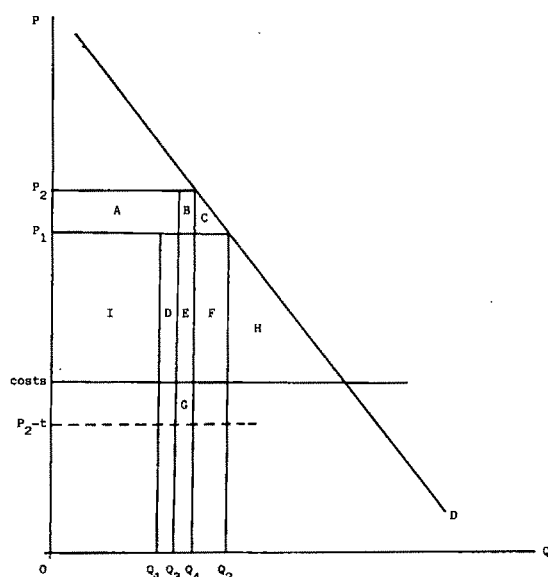

Figure 1. Fertilizer market analysis

¹ The outcome of this game is sensitive to the strategic variable because optimal policies may depend upon whether firms play Cournot (quantity strategies) or Bertrand (price strategies). Eaton and Grossman have shown that, for an exporter, Cournot conjectures would imply an optimal export subsidy while Bertrand conjectures would lead to an optimal export tax. However, in the context of an import market, tariffs are optimal for both Cournot and Bertrand conjectures, though, as Cheng has shown, the values for the optimal tariffs will differ.

Structural Characteristics of the Fertilizer Industry

While it is difficult to generalize, the fertilizer industry in many developed countries tends to be concentrated in nature. Access to raw materials such as natural gas, the capital-intensive nature of production, and economies of scale often create barriers to entry. Within the EC one or two dominant firms co-exist with a "competitive" fringe of smaller firms who blend fertilizers for local and regional markets (European Commission). For example, in the UK three firms now account for 80% of the market (UK Census of Production), with ICI taking just over 50%. Elsewhere in the EC, Ercros accounts for 60% of the Spanish market (*Financial Times*), BASF and Norsk Hydro (formerly VEBA) dominate the West German market, while Cdf Chemie and Norsk Hydro (formerly COFAZ) account for a substantial share of the French market (European Commission). The U.S. fertilizer industry is less concentrated (Leibensluft), with eight firms taking a 57% market share in 1982 (U.S. Census of Manufactures). Pressure from imports in the 1980s has forced some plant closures in the United States, which may have led to increased seller concentration (Daberkow).

In terms of market behavior and performance, there is some evidence that firms in developed countries have acted less than competitively. Shaw has traced price and product competition in the UK fertilizer industry in the postwar period, finding evidence for periods of oligopolistic accommodation as characterized by parallel pricing, interspersed by the occasional price war. Bayri, Rosaasen, and Furtan indicate that Canadian manufacturers have set prices in order to limit entry and maintain above-normal profits. However, the ability of firms to act less than competitively has been constrained by recent changes in the world fertilizer market. A shift in supply away from developed Western countries to developing and Eastern bloc countries has placed the former under greater competitive pressure. In particular, the EC market has been characterized by an inflow of low-priced imports (Agra Europe) resulting in increased demands by EC firms for protection from the predatory pricing tactics of non-EC firms.

Given these structural characteristics a *prima facie* case can be made for applying the theoretical arguments for government intervention when markets are imperfectly competitive to the fertilizer industry. However, as the structure of

the industry changes, so too should the extent of government intervention. For example, as the fertilizer industry becomes less competitive as a result of a change in its economic environment, one would expect a priori change in the level of the tariff and subsidy values for the policies to remain optimal. Typically, the factors affecting the fertilizer industries in developed countries in recent years have included changes in the number of fertilizer manufacturers, changes in costs (e.g., energy, wages, etc.) and increased competition from third-country exporters (dumping).

Derivation of Optimal Policies

The theoretical underpinnings for this paper are based upon Dixit (1988) and are fully explained in the appendix. The essential features of the model are as follows: the structure of the UK fertilizer market is divided into two, where subscript 1 refers to the dominant firms and subscript 2 refers to the blenders who act primarily as importers of urea (a substitute for ammonia); domestically produced fertilizers and imports are considered imperfect substitutes in agricultural production, these products being differentiated by nitrogen content per tonne; firm behavior is modeled as a Nash equilibrium in conjectural variations, although no explicit behavior (e.g., Cournot) is imposed on the model.

National welfare is the sum of farmers' producer surplus (Γ), the dominant firms' profits (Π_1) and government revenue/expenditure (t and s , where t is a tariff and s is a production subsidy, the proxy for antitrust policy), as given by

$$(1) \quad W = \Gamma + \Pi_1 + (tQ_2 - sQ_1).$$

The government's objective is to choose values for t and s that maximize national welfare. Essentially, the government has three policy choices: first, it can calculate a value for the optimum tariff without a production subsidy ($s = 0$); second, it can derive a value for the optimal production subsidy without a tariff ($t = 0$); or, finally, it can choose a joint policy combination. In the latter case, one policy will likely, in part, substitute for the role played by the other.

The optimal tariff without a subsidy is found by maximizing welfare with respect to t . Following Dixit, this gives an expression for the optimal tariff as

$$(2) \quad t = Q_2V_2 + (Q_1V_1)k/(b_1 + V_1).$$

Substituting for Q_1 and Q_2 from (A13), the explicit expression for the optimal tariff is

$$(3) \quad t = \frac{(a_1 - c_1)k(\beta_2 V_1 - \beta_1 V_2) + (a_2 - c_2)(\beta_1^2 V_2 - k^2 V_1)}{\beta_1^2(\beta_2 + V_2) - k^2(\beta_1 + V_1)},$$

where $\beta_i = (b_i + V_i)$.

The values for a_i , b_i , and k are taken from the inverse demand equations as shown in (A5) and (A4). The value for the optimal tariff is, therefore, dependent on the nature of competition in the market (V_i) and relative costs between the home industry and its competitors. With respect to firms' behavior, the higher the value for V_i , the higher the value of the optimal tariff. Intuitively, a high V_1 suggests that the home industry has market power. A higher V_2 suggests higher supernormal profits for the foreign industry. Thus, high values for V_i suggest a stronger role for tariffs in order to shift profits from the foreign industry to the home country.

The other determinant of the optimal tariff value is relative costs. In particular, since $(\beta_1^2 V_2 - k^2 V_1)$ is likely negative and $(\beta_2 V_1 - \beta_1 V_2)$ is positive, assuming that the values for a_i are similar, then differences between home and foreign costs are important. Thus, a home industry with a cost advantage strengthens the argument for a tariff, while a foreign industry with a cost advantage weakens the argument for a tariff. However, if costs are sufficiently similar and the two types of fertilizer are sufficiently imperfect substitutes for each other, then an optimal tariff will be justified.²

The optimal production subsidy is derived in a similar way to the tariff. Maximizing welfare with respect to s gives

$$(4) \quad s = Q_1 V_1 + (Q_2 V_2)k / (b_2 + V_2),$$

and substituting for Q_1 and Q_2 from (A12) gives

$$(5) \quad s = \frac{(a_1 - c_1)(\beta_2^2 V_1 - k^2 V_2) + (a_2 - c_2)k(\beta_1 V_2 - \beta_2 V_1)}{\beta_2^2(\beta_1 - V_1) + k^2(V_2 - \beta_2)},$$

where β_i is defined as above.

Again, government policy will vary with costs and the conjectural variations parameters. The lower the values for V_i , the lower the value for s ; i.e., because the market is tending towards perfect competition, there is less need for s to overcome the competitive distortion. The greater

the cost advantage of the home firm, the greater is the need for a production subsidy.

The joint optimum is derived by maximizing (1) with respect to t and s . Thus, the optimum tariff when s does not equal zero is

$$(6) \quad t = \frac{-(a_1 - c_1)kV_2 + (a_2 - c_2)b_1V_1}{(b_2 + 2V_2)b_1 - k^2}.$$

Similarly, the optimal subsidy when t does not equal zero is

$$(7) \quad s = \frac{(a_1 - c_1)V_1(b_2 + 2V_2) - (a_2 - c_2)kV_1}{(b_2 + 2V_2)b_1 - k^2}.$$

The determinants of the joint optimum tariffs and subsidies follow the intuition outlined above.

Adjustment of Policies to Structural Change

As indicated in section two, the fertilizer industry in developed countries is subject to frequent pressures. Thus, given that there is a normative justification for government intervention (in one form or another), it is worthwhile to consider how these policies should vary when the structural characteristics, i.e., c_i and V_i , of the fertilizer industry change. In particular, the effects of firm exit from the fertilizer industry are emphasized in this section.

Exit of firms from the market, say through take-over by a competitor, has been a recurring characteristic of structural change in the Euro-

pean fertilizer industry.³ In the UK market, the number of dominant firms has recently fallen from four to three as one firm (UKF) swapped its production facilities with Kemira in exchange for capacity in the Dutch market. Exit,

² Cheng has analyzed the possibility of corner solutions when costs are sufficiently differentiated and products are homogenous.

³ Particularly notable are the activities of the Norwegian-based Norsk-Hydro, which has acquired production capacity in most countries in Western Europe (McCorriston and Sheldon).

which will increase seller concentration, can be captured by a fall in n_1 . Hence, given $V_1 = -b_1/n_1$, the fall in the number of firms n_1 will lead to an increase in V_1 . Because the change in V_1 will be reflected in a change in p_1 , the change in the optimal tariff is obtained by deriving dt/dV_1 and dp_1/dV_1 to give

$$(8) \quad \left. \frac{dt}{dp_1} \right|_{s=0} = \frac{k\Delta'[\beta_2(\Delta' - 2\beta_2V_1) + V_2\Delta' - (2V_2\beta_1 - k^2)]}{2(\beta_2b_1 - k^2)[\beta_1^2(\beta_2 + V_2) - k^2(\beta_1 + V_1)]},$$

where $\Delta' = (\beta_1\beta_2 - k^2)$, and

$$(9) \quad \left. \frac{dt}{dp_1} \right|_{s \neq 0} = \frac{b_1(a_2 - c_2)\Delta'}{[(b_2 + 2V_2)b_1 - k^2]2Q_1(\beta_2b_1 - k^2)},$$

where Δ' is given as above and Q_1 is the initial level of output.

By a similar procedure, the change in the optimal subsidy will be given as

$$(10) \quad \left. \frac{ds}{dp_1} \right|_{t=0} = \frac{\Delta'(2b_2 + V_2)}{2(\beta_2b_1 - k^2)\beta_2^2b_1 - k^2b_2}, \text{ and}$$

$$(11) \quad \left. \frac{ds}{dp_1} \right|_{t \neq 0} = \frac{[(a_1 - c_1)(b_2 + 2V_2) - k(a_2 - c_2)]\Delta'}{[(b_2 + 2V_2)b_1 - k^2]2Q_1(\beta_2b_1 - k^2)},$$

where Δ' and Q_1 are as defined above.

Because the rise in V_1 is indicative of greater concentration in the fertilizer industry, the value for both optimal policies is expected to increase.

Besides exit of firms, other changes in market structure will also affect the values of optimal policies. These will include changes in domestic and foreign firms' costs and the behavior of foreign firms. The direction of policy adjustments is summarized in table 1. The structural changes shown have been typical of those that have affected the European fertilizer industry in recent years; domestic costs have fallen because of increased technical efficiency; exporters' costs have

fallen as a result of government subsidies (European Commission); lower oil prices in the mid-1980s reduced both the costs of domestic and foreign firms; and accusations of dumping by exporters characterizes changes in foreign competitors' behavior.

Model Calibration

In order to quantify the optimal policies outlined above, estimates of the parameters in the demand system (A3) and (A4) are needed. However, equations (A5) and (A6) indicate five unknowns (A_1 , A_2 , B_1 , B_2 , and K) but only two relations between them. Consequently, three further relations are required to solve the system. Following Dixit (1987), expressions for the elasticities of demand and substitution are derived and set equal to empirically observed values.

Because the products of the dominant firms and of the blenders are treated as imperfect substitutes, the price elasticity of demand is interpreted as the effect of an equiproportionate rise in the price of the two products on total fertilizer expenditure Q . Therefore letting $p_1 = P_1^0P$ and $p_2 = P_2^0P$, where P_1^0 and P_2^0 are initial prices and P is the proportional change factor, the aggregate expenditure for fertilizers can be written as

$$(12) \quad Q = P_1^0Q_1 + P_2^0Q_2.$$

Given that p_1 and p_2 are the initial prices in the calibration, and substituting equations (A5) and (A6) into (28), the aggregate expenditure index can be written as

$$(13) \quad Q = p_1A_1 + p_2A_2 - (B_1p_1^2 + B_2p_2^2 - 2Kp_1p_2)P.$$

Table 1. Adjustment of Policies to Structural Change

	Tariff ($s = 0$)	Subsidy ($t = 0$)	Tariff ($s \neq 0$)	Subsidy ($t \neq 0$)
Domestic firm ceases production (exit)	+	+	+	+
Domestic costs fall	+	+	+	+
Foreign firms' costs are subsidized	+	-	+	-
Exogenous fall in energy costs	+	+	+	+
Dumping by foreign exporters	-	-	-	-

Note: The derivation of these policy adjustments are available from the authors on request.

The total market elasticity of demand for fertilizer, ϵ , is then defined and evaluated at the initial point where the proportional change factor P equals 1. By differentiating (13) with respect to P and multiplying by P/Q , the elasticity is given as

$$(14) \quad \epsilon = - \frac{B_1 p_1^2 + B_2 p_2^2 - 2K p_1 p_2}{Q}$$

Expression (14) is then set equal to the observed value of ϵ .

The elasticity of substitution would normally be defined as

$$(15) \quad \sigma = d \log(Q_1/Q_2) / d \log(p_1/p_2),$$

which gives a fourth relation between the parameters when set equal to an empirically observed value for σ . However, equations (A5) and (A6) in general define the ratio Q_1/Q_2 as a function of the vector (p_1, p_2) and not in terms of the ratio p_1/p_2 . In order for Q_1/Q_2 to be a function of p_1/p_2 , at least locally, the parameters must satisfy the following final relation:

$$(16) \quad p_1(A_1 K + A_2 B_1) = p_2(A_2 K + A_1 B_2),$$

which implies homotheticity of the production function. Given the definition of σ in (15) and using equations (A5), (A6), and (16), the final expression for the elasticity of substitution can be derived as

$$(17) \quad \sigma = \frac{\frac{p_1}{p_2} (B_1 B_2 - K^2)}{\left(B \frac{p_1}{p_2} - K \right) \left(B_2 - K \frac{p_1}{p_2} \right)}$$

The simultaneous equation system using (A5), (A6), (14), (16), and (17) is solved to obtain estimates of A_1 , A_2 , B_1 , B_2 , and K where prices and quantities and estimates of the elasticity of demand and substitution are taken from outside sources. This solution reflects the process of model calibration such that the parameters are consistent with equilibrium in any given period. Values for a_1 , a_2 , b_1 , b_2 , and k can now be derived. Because of the limited availability of data, the model was calibrated for the UK fertilizer market for the year 1985: p_1 (£126) and p_2 (£120) are the average selling prices of the dominant firms and blenders, respectively, over the year 1986 based on reported prices in the UK farming press; Q_1 and Q_2 (1,268 and 317 thousand tonnes, respectively) are derived from Fertilizer Manufacturers Association data and other farm-

ing and trade sources. The elasticity of demand ϵ (assumed to be -0.65) is based on an estimate made by Metcalf and Cowling, although more recent estimates by Burrell suggest a similar value. No estimate of σ is available for the UK, so a value of 2.00 was assumed; the 2.00 value compares with an Australian estimate made by Higgs of 1.7. The cost estimates are £100 for c_1 , for the dominant firms based upon reported cost levels in Challinor and the UK farming press, and c_2 at £110 representing blenders' operating costs, which are assumed to be £10 below the selling price p_2 . The parameter estimates for the model are shown in table 2.

Welfare Effects of Government Intervention

To recap the discussion in the first section, if markets (home and foreign) are characterized by imperfect competition an activist trade policy may increase national welfare. However, production subsidies may represent a superior policy instrument, although a combination of tariffs and subsidies may be the most desirable policy. Using the calibrated parameters and cost information, values for the optimal tariff and subsidy policies were derived from (3), (5), (6), and (7), respectively.

In line with the theoretical predictions the optimal tariff has a value of £18.21 per tonne of fertilizer. However, the optimal production subsidy is £31.79 per tonne. When the tariff and subsidy are chosen simultaneously, the policies in part substitute for each other. The optimal tariff is now £2.71 per tonne, while the optimal subsidy is reduced to £30.38 per tonne. Solving for the new prices and quantities following the imposition of policy using (A3), (A4), and (A11), and (A12), the effects on national welfare can be estimated using (1). The results are presented in table 3 and are compared with the prepolicy welfare.

As the new trade theory predicts, the optimal tariff should increase overall welfare. However,

Table 2. Demand Parameters

Aggregate Demand Functions		Inverse Demand Functions	
A_1	2,092,200	a_1	320
A_2	523,050	a_2	305
B_1	7799	b_1	(10^{-4}) 1.38
B_2	3104	b_2	(10^{-4}) 3.47
K	1321	k	(10^{-5}) 5.88

Table 3. Welfare Effects of Optimal Tariff and Subsidy Policies (£m)

	Farmers' Welfare	Dominant Firms' Profits	Government Revenue/Expenditure	Overall Welfare
Pre-policy welfare	152.36	32.97		185.33
Welfare with optimal tariff ($t = £18.21$)	147.23	34.06	4.86	186.15
Welfare with optimal subsidy ($s = £31.79$)	183.49	48.93	-43.90	188.52
Welfare with joint optimal tariff and subsidies ($t = £2.71, s = £30.38$)	181.47	50.08	-43.03	188.53

the overall welfare gains are small (0.44% relative to the prepolicy case) and mainly involve a redistribution of welfare from farmers' to the dominant firms and the government. However, as expected, the optimal production subsidy leads to a higher level of economic welfare by countering the competitive distortion in the fertilizer market.⁴ The net welfare gains, in this case, although still low (1.77% relative to the prepolicy case) are larger than those resulting from the optimal tariff. The joint use of the tariff and subsidy policies is only marginally superior to using the subsidy alone.

Despite the small net welfare changes, the optimal production subsidy leads to a considerable redistribution of welfare between farmers, the dominant fertilizer manufacturers, and the government. In particular, because the optimal subsidy counters the oligopolistic distortion, farmers' welfare increases as a result of the lower prices for fertilizers. Essentially, farmers' producer surplus increases by around £36m in 1985 or by 25% relative to prepolicy welfare. The dominant firms' profits also increase substantially (by 43%), while the government must pay for the subsidy. Although the welfare gain arising from the joint policies is only marginally better than using the subsidy alone, the main difference between these two cases involves the distribution of income. Farmers' gains are lower and the dominant firms' profits greater in the joint optimum case relative to using the subsidy alone. The sensitivity of the results to the data used to calibrate the model is considered below.

Elasticity Data

Model calibration relies upon estimates of the elasticities of demand and substitution. In order to analyze how sensitive the results are to changes

in these elasticities, different values for ϵ and σ were chosen. The corresponding optimal policies and welfare outcomes are presented in table 4.

The central column shows the base results derived above. As the elasticities increase (in absolute terms), the values for the optimal tariffs and subsidies increase, except for the value of the tariff in the joint optimum. However, the ranking of the policies is not sensitive to the elasticity data. Specifically, tariffs lead to a very small increase in national welfare, although more substantial increases accrue from the subsidy policy. Again, the joint optimum case is better, but only marginally so, relative to the subsidy alone.

Economies of Scale

An important feature of the fertilizer industry in developed countries is scale economies. In the model's derivation, however, this feature largely was ignored because of the problem of allocating capital costs intertemporally in the cost function. Nevertheless, it is still interesting to enquire whether the results are sensitive to firms reaping economies of scale.

An external estimate of economies of scale is used to determine how far costs may fall as output increases as a result of the various policies. Unfortunately Pratten (the main source of information on UK and European economies of scale) provides no estimate for the fertilizer industry. Instead, it is assumed that the extent of scale economies in the fertilizer industry is similar to that in the petrochemical industry which implies a cost elasticity of 20% (Pratten). With this proxy estimate, the likely changes in firms' profits (the main source of benefit arising from the scale economies) was estimated for the various forms of government intervention. The results are presented in table 5.

The results from table 5 suggest that an allowance for (extensive) economies of scale would

⁴ In practice, the welfare effects of antitrust legislation would not involve the transfer of a subsidy payment from government to producers.

Table 4. Sensitivity Analysis: Changes in Elasticity Data

		$\epsilon = -0.5$ $\sigma = 1.75$	$\epsilon = -0.65$ $\sigma = 2.00$	$\epsilon = -0.80$ $\sigma = 2.75$
Pre-policy welfare	(£m)	230.78	185.33	156.60
Optimal tariff	(£)	16.88	18.21	26.60
Welfare with tariff	(£m)	231.10	186.15	157.44
Optimal subsidy	(£)	30.36	31.79	33.83
Welfare with subsidy	(£m)	232.90	188.52	160.75
Joint optimum:				
Tariff	(£)	3.70	2.71	0.22
Subsidy	(£)	29.18	30.38	31.96
Welfare with joint optimum	(£m)	232.95	188.53	160.75

Table 5. Sensitivity Analysis: Economies of Scale (Cost Elasticity = 0.2)

	Domestic Firms' Profits ^a (£m)	
	No Economies of Scale	Economies of Scale
Optimal tariff	34.06	34.09
Optimal subsidy	48.93	51.01
Joint optimum	50.98	50.28

^a Original profits were £32.97m.

not significantly affect the welfare calculations. The greatest change in the firms' profits occurs for the optimal subsidy; profits increase by 54.7% when costs decrease compared with 48.4% when costs remain constant. This 54.7% increase in profits translates into a 2.8% increase in welfare (relative to the prepolicy levels) compared with a 1.72% increase in welfare in the constant costs case.

Cost Estimates

Finally, because the level of costs is important in determining the level of the policy variable, it is important to consider how sensitive the policy values are to changes in costs. The focus is on changes in the tariff values (in the absence of the subsidy) in response to changes in the costs of the domestic firms.

Two cases are compared with the base outcome. The first is where the costs are lower than the original case (£90 per tonne as opposed to £100 per tonne), and the second is where the domestic firms' costs are equal to those of the importers (i.e., £110 per tonne). The corresponding values for the tariff levels are shown in table 6. The results indicate that the value for

Table 6. Sensitivity Analysis: Effect of Changes in Domestic Firms Costs on Tariff Levels (£)

	$c_1 = 90$	$c_1 = 100$	$c_1 = 110$
Optimal tariff ($s = 0$)	21.11	18.21	15.02

the optimal tariff increases (decreases) as costs rise (fall). Similar results occur for the optimal subsidy. These results imply that higher costs are associated with more competitive conduct (lower V_i) and, therefore, less need for government intervention.

In sum, government intervention in the fertilizer industry can be normatively justified. The sole use of tariffs is an inferior policy relative to antitrust policy (optimal subsidies), although the best outcome (though only marginally so) is achieved by the joint use of tariffs and subsidies. While the overall increase in welfare (assuming equal weights between the various groups) is generally small, the main effect of these policies is on the distribution of income, particularly between farmers and the domestic fertilizer manufacturers. Farmers would gain substantially from antitrust legislation, while their welfare would be significantly reduced from (optimal) trade policy intervention.

Optimal Policies and Changes in Market Structure

These optimal policies likely will vary as market structure changes. Therefore, following the earlier analysis of section 4, values for the optimal policy responses to various market scenarios are presented in table 7. The values in table 7 represent response by tariffs or subsidies

Table 7. Tariff and Subsidy Policy Changes as Market Structure Varies (per unit change)

	Tariff ($s = 0$)	Subsidy ($t = 0$)	Tariff ($s \neq 0$)	Subsidy ($t \neq 0$)
Domestic firm ceases production (exit)	1.28	0.121	0.2315	0.2592
Domestic costs fall	0.019	0.152	4.62 ⁻⁰⁶	0.1582
Foreign firms' costs are subsidized	0.074	-0.009	0.0533	-0.0227
Exogenous fall in energy costs	0.143	0.093	0.0184	0.1355
Dumping by foreign exporters	-0.504	-0.121	-0.4956	-0.0269

to a unit change in, say, domestic costs. All policy responses fulfill the a priori expectations outlined above. For example, if foreign firms' costs are subsidized by their government, an increase in tariff would countervail this subsidy. However, due to the assumption of a constant price-cost mark-up for the blenders, the lower costs are reflected in lower market prices. Hence, imports provide a procompetitive discipline on the fertilizer market. When foreign firms dump their fertilizer exports on the market, both policy values should fall as a result of the competitive effect on the market. The other scenarios imply that the tariff and subsidy values should increase because the market is less competitive. In the joint optimum case, changes in the tariff are lower relative to changes when the tariff is the sole policy. However, except for dumping by foreign exporters, changes in the subsidy levels were greater in the joint optimum case compared to the subsidy case alone.

These results imply that, given the normative case for government intervention in the fertilizer industry, the levels of government intervention should adjust to change in the fertilizer market; however, the extent of the adjustment depends upon the source of change in the fertilizer market.

Consider an example where the focus is on changes in the level of welfare (following a change in market structure) if the government did not change the policy value relative to the case of fine-tuning its policy. The example is a domestic fertilizer manufacturer that ceases production. This scenario is representative of the UK market when UKF, one of four dominant domestic firms, ceased operation in the UK in 1988. The welfare effects of the UK government adjusting and not adjusting its intervention policies are shown in table 8.

In the benchmark case the government is initially using optimal tariffs and/or subsidies. If, as firms exit, the government did not change the policy values, economic welfare would be reduced in all cases. Thus, in the case of using the tariff alone, with no change in the optimal tariff, welfare would fall by 5.3%. The corresponding changes in welfare in the optimal subsidy and joint optimum cases are -0.75% and -2.7%, respectively. However, if the government did change the policy values by the extent recorded in table 7, then the optimal tariffs and subsidies would rise in all cases (given that the fertilizer market is now less competitive). The effects of these changes are either that the welfare losses are minimized (as in the case of us-

Table 8. Effects of Firm Exit

	Welfare £m	Percent Change Relative to No-Exit Case
<i>Tariff: $t = £18.21$</i>	186.15	
Exit: $t = £18.21$	176.23	-5.3
Exit: $t = £57.71$	183.54	-1.4
<i>Subsidy: $s = £31.79$</i>	188.52	
Exit: $s = £31.79$	187.11	-0.75
Exit: $s = £35.54$	188.57	0.03
<i>Joint optimum: $t = £2.71, s = £30.38$</i>	188.53	
Exit: $t = £2.71, s = £30.38$	183.51	-2.7
Exit: $t = £9.8, s = £38.40$	189.65	0.6

ing the tariff alone) or economic welfare is marginally increased (as shown in the optimal subsidy and joint optimum cases).

In sum, failure to change the optimal policy values in response to changes in market structure may lead to significant welfare losses. Thus, if government intervention in agricultural input markets is warranted, then the extent of intervention should respond to changes in the economic and policy environment.

Concluding Comments

Fertilizer manufacturers in developed countries often demand support from their home governments to improve the competitiveness of their industry or to protect it from external pressures. By applying the recent developments in the international economics literature, it has been shown that governments may use an optimal tariff to protect their domestic producers on the grounds that rents can be shifted from their international competitors. However, a stronger case exists for governments to use an optimal production subsidy (a proxy for antitrust policy) to counter the oligopolistic distortion in the fertilizer industry. The best policy is to use tariffs and subsidies together.

These theoretical results were validated by providing quantitative estimates for these policies for the UK fertilizer market. While the net welfare changes were small, both policies involved a substantial redistribution among farmers, the dominant firms, and the government. Farmers would experience substantial gains if antitrust policy promoted greater competition in the market, while considerable losses would occur under an optimal tariff. Using both policies simultaneously improves welfare only marginally more than using the subsidy alone, though the benefits to farmers are slightly less. Further, it was argued that governments should remain active following the initial imposition of the optimal policies. In particular, as the market becomes more (less) competitive, the optimal tariff and subsidy values should fall (increase).

The overall conclusion of this paper is that agricultural economists should pay more attention to the demands for government support that originate in the agricultural inputs sector. In particular, while there may be a normative justification for government protection against imports, higher levels of economic welfare can be attained if governments counter the competitive

distortion that is characteristic of many agricultural input markets.

Appendix

Theoretical Framework

The theoretical framework for this paper is based upon Dixit (1988). The structure of the UK fertilizer market is divided into two, where subscript 1 refers to the dominant firms and subscript 2 refers to the blenders, who act as importers of urea (a substitute for ammonia). Because the blenders are treated as import agents, for simplicity they do not enter into the national welfare function. Initially, no entry/exit of firms occurs. Further, the dominant firms face constant average and marginal operating costs and blenders have a constant price-cost mark-up. Also, domestically produced fertilizers and imports are considered imperfect substitutes in production because these products have different nitrogen content per tonne.

Fertilizer market. Farmers' demand for fertilizers can be derived by maximizing the following profit function Γ for farmers with respect to Q_1 and Q_2 :

$$(A1) \quad \Gamma = f(Q_1, Q_2) - p_1 Q_1 - p_2 Q_2,$$

where the aggregate production function $f(Q_1, Q_2)$ for farmers is defined as

$$(A2) \quad f(Q_1, Q_2) = a_1 Q_1 + a_2 Q_2 - 1/2 (b_1 Q_1^2 + b_2 Q_2^2 + 2k Q_1 Q_2).$$

For simplicity, this production function is of quadratic form, no inputs other than the two forms of fertilizer Q_1 and Q_2 are considered, and farmers' output prices are normalized to one.

The farmers' profit function can be used to derive the respective inverse demand functions for the dominant firms and blenders, as given below:

$$(A3) \quad p_1 = a_1 - b_1 Q_1 - k Q_2, \text{ and}$$

$$(A4) \quad p_2 = a_2 - k Q_1 - b_2 Q_2,$$

where all parameters are positive, $(b_1 b_2 - k^2) > 0$ since

the products are imperfect substitutes, p_1 and p_2 are prices, and Q_1 and Q_2 are quantities. The corresponding demand functions are given as

$$(A5) \quad Q_1 = A_1 - B_1 p_1 + K p_2, \text{ and}$$

$$(A6) \quad Q_2 = A_2 + K p_1 - B_2 p_2,$$

where $B_1 B_2 - K^2 > 0$.

On the fertilizer production side, n_i firms are in each sector of the industry. Profits for a representative firm are given by

$$(A7) \quad \Pi_1 = (p_1 - c_1 + s) q_1 - f_1, \text{ and}$$

$$(A8) \quad \Pi_2 = (p_2 - c_2 - t) q_2 - f_2,$$

where prices and quantities are defined above, c_i is the marginal operating costs, and f_i is fixed costs.⁵ A production subsidy is given to the firm in the dominant sector of the market (the home firm), and t is a tariff on imports from foreign competitors.

The behavioral assumption is that firms' reactions to one another are treated as a Nash equilibrium with conjectural variations which arise from the firms' profit functions. Despite the problems with this approach, using conjectural variations in this model requires no explicit form of oligopolistic interdependence. Rather, the values of these parameters come from the data.

The conjectural variation parameter is derived from the first-order condition of the respective profits functions as given below:

$$(A9) \quad p_1 - c_1 + s + q_1 dp_1/dq_1 = 0, \text{ and}$$

$$(A10) \quad p_2 - c_2 - t + q_2 dp_2/dq_2 = 0,$$

where dp_i/dq_i is the conjectural variation parameter, i.e., the firm's expectation of how market price will vary with changes in output. Therefore, if a representative firm plays Cournot, it believes rival firms will not change output in response to a change in q_i ; hence, $dp_i/dq_i = -b_i$, the slope of the inverse demand function. If the market were perfectly competitive, a change in one firm's output would have no effect on market price, i.e., $dp_i/dq_i = 0$.

These first-order conditions for representative firms can be aggregated over n_i firms in each sector of the industry to give

$$(A11) \quad p_1 - c_1 + s + Q_1 V_1 = 0, \text{ and}$$

$$(A12) \quad p_2 - c_2 - t + Q_2 V_2 = 0,$$

where V_i is the aggregate conjectural variations parameter. Thus, for Cournot behavior, $V_i = -b_i/n_i$, and, as n_i increases, the more competitive the Cournot outcome becomes. In the limit $V_i = 0$, i.e., perfect competition.

Equilibrium prices and quantities in this fertilizer market model are obtained by combining (A3) and (A4) with (A11)

⁵ The profits functions in (A7) and (A8) include fixed costs. However, because data on this component of costs are not available, it is assumed that operating costs include fixed costs.

and (A12). Explicit solutions for prices and quantities are given below:

(A13)
$$\begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} = \frac{1}{\Delta'} \begin{bmatrix} b_2 + V_2 & -k \\ -k & b_1 + V_1 \end{bmatrix} \begin{bmatrix} a_1 - c_1 + s \\ a_2 - c_2 - t \end{bmatrix}$$

$\begin{bmatrix} a_1 - c_1 + s \\ a_2 - c_2 - t \end{bmatrix}$, and

(A14)
$$\begin{bmatrix} p_1 \\ p_2 \end{bmatrix} = \begin{bmatrix} a_1 \\ a_2 \end{bmatrix} - \frac{1}{\Delta'} \begin{bmatrix} \Delta + b_1 V_2 & k V_1 \\ k V_2 & \Delta + b_2 V_1 \end{bmatrix} \begin{bmatrix} a_1 - c_1 + s \\ a_2 - c_2 - t \end{bmatrix}$$

where $\Delta = (b_1 b_2 - k^2)$ and $\Delta' = (b_1 + V_1)(b_2 + v_2) - k^2 = (\beta_1 \beta_2 - k^2)$.

Supply Impact of the Milk Diversion and Dairy Termination Programs

Bruce L. Dixon, Dwi Susanto, and Calvin R. Berry

A two-equation random coefficient regression model of commercial milk production is estimated using monthly observations from 1983 through June 1988 for the twenty-one major milk-producing states in the United States. Policy variables are entered into the model to represent the impact of the Milk Diversion Program (MDP) and the Dairy Termination Program (DTP). The MDP was primarily short term in impact and the DTP has been longer term. The DTP provision banning producers who exited under the program from producing for five years appears to have been ineffectual. The programs' effectiveness across states has varied considerably.

Key words: milk diversion and termination program effectiveness, random coefficients.

For over thirty-five years the U.S. dairy industry has been characterized by intensive government interventions. Under this regulation, the industry has provided adequate quantities of milk at relatively stable producer and consumer prices (Whipple, Powe, and Gray; Berry and Blakley). However, the situation changed during the early 1980s when the dairy industry began producing expanding surpluses. Milk production has been showing a steady tendency to rise.

The increase in milk production resulted in large government outlays through the dairy price support program or other incentives (Whipple, Powe, and Gray). A reduction in the price support level and a per hundredweight assessment were legislated in 1983. The purposes of these actions were to reduce milk production by lowering producer prices and to support promotion and product development.

Two major voluntary supply control programs, the Milk Diversion Program (MDP) and the Dairy Termination Program (DTP), were implemented in the mid-1980s. The MDP compensated dairy farmers who contracted to restrict their output by 5% to 30% of their historical base by paying them \$10 per hundredweight for the contracted reduction from their historical base. The MDP was in effect from 1 January

1984 through 31 March 1985. Dairy farmers subscribed to remove 7.5 billion pounds (Miller and Carman) of production on an annual basis.

The DTP required that producers whose bids were accepted sell or export all of their female dairy cattle. Moreover, the dairyman could have no interest in milk production for the ensuing five years, nor could his facilities be used for milk production in the five-year period. In addition to selling the entire herd for either slaughter or export, the farmer received a payment from the government. This payment was based on the bid per hundredweight (cwt.) of milk reflected in the farmer's offer in return for exiting the industry for at least five years. The bid averaged approximately \$15.00 per hundredweight of annual production for the U.S. (Matthews). These bids were accepted on a competitive basis nationwide and resulted in 11.3 billion pounds of annual capacity exiting the industry between April 1986 and August 1987 (ASCS, personal communication).

Both the MDP and DTP were intended to decrease the production of milk. Consequently, it is important to determine the short- and longer-term impacts of these programs on milk production. Because milk supply is likely to increase in the future, especially considering the introduction of bovine somatotropin (Kaiser and Tauer), it is important to measure the effectiveness of past programs since they are possible candidates for future programs. Moreover, because of the heterogeneity of the dairy industry across the United States, it is important to measure the diversity of the impacts by region.

Bruce L. Dixon and Calvin R. Berry are professors of agricultural economics, Department of Agricultural Economics and Rural Sociology, University of Arkansas; Dwi Susanto is a lecturer at the University of Lampung, Indonesia.

The computing assistance of Siew Goh and Diana Danforth is gratefully acknowledged, as are the helpful comments of the *Journal* referees.

To estimate the impact of the MDP and DTP, a two-equation model is specified and estimated using time-series and cross-sectional data. The first equation is yield per cow, and the second equation is cow numbers. Data are monthly for each of the twenty-one states listed by the U.S. Department of Agriculture (USDA) as the major milk-producing states in the United States. Using monthly data provides for a much more accurate measure of program effectiveness since the MDP lasted only fifteen months, and the exit period for the DTP lasted seventeen months. Hence, models using annual or quarterly data would have greater difficulty capturing the dynamic responses engendered by the programs. Both equations are specified as Swamy random coefficient regressions (RCR).

In what follows, an econometric model of commercial milk production is specified and estimated. The forecasting ability of the model is verified through a post-sample prediction experiment. The model is used to simulate milk production, first under the assumption that both the MDP and DTP were in effect, then second that only the MDP was implemented, and third, assuming only the DTP was implemented. A fourth simulation assumes neither were implemented and compares production with the predicted production when the various combinations of programs were implemented. Implications of these simulations are then considered.

Model Specification

Following prior studies (Wilson and Thompson; Chen, Courtney, and Schmitz; Kaiser, Streeter, and Liu) commercial milk production is modeled as the product of number of cows freshened (*CN*) and production per cow (*PPC*). Both equations are double logarithmic. The *CN* equation is a function of the ratio of the blend price of milk to the price of 16% protein dairy feed (*MFPR*), both variables lagged one month, variables representing the amount of base production withdrawn during the two programs, and a lagged dependent variable. Algebraically the *CN* equation is written as

$$(1) \quad \ln(CN)_{it} = \alpha_0 + \alpha_1 MDP_{it} + \alpha_2 DTP_{it} + \alpha_3 \ln(MFPR)_{i,t-1} + \alpha_4 \ln(CN)_{i,t-1} + w_{it}.$$

Subscript *i* refers to the state *i*, *t* refers to the month *t*, and \ln denotes natural logarithm. The error term, w_{it} , is specified to have zero mean and to be homoscedastic within a given state but

heteroscedastic across states. *MDP* is the amount of a state's production base on a fifteen-month basis entered into the diversion program in billions of pounds. It has the same value for each month between January 1984 through March 1985 and zero otherwise. Variable *DTP* is the annual base production deleted, by state, in billions of pounds under the *DTP*. The variable *DTP* is structured as a cumulative variable since the termination program was subdivided into three exit periods (4/86–8/86, 9/86–2/87, and 3/87–8/87). Producers could submit bids for any or all of the periods but had to exit during the period associated with the accepted bid. *DTP* is zero for all observations prior to 4/86. From 4/86–8/86 it is the state's base exiting during the first period. From 9/86–2/87 it is the sum of a state's first and second periods' base production exiting. From 3/87–8/87 it is the total base exiting during the termination program. From 9/87 forward *DTP* is zero.

A reasonable argument can be made that the *DTP* variable should not become zero after the exit period but continue to have nonzero values because exited farmers under the DTP could not resume production for five years after exiting. As discussed in the results section, this seemingly more orthodox specification gave inferior results. Price of slaughter cows, which has been included in prior studies (e.g., Kaiser, Streeter, and Liu; LaFrance and de Gorter) is not included in (1). In all specifications examined, this price had a positive and significant coefficient which is contrary to expectations. This likely results from the fact that both dairy cows and beef cows were in a liquidation phase of the cattle cycle from 1983–88, the sample period used for estimation and prediction.

PPC is a function of the *MDP*, lagged *MFPR*, monthly binary variables to account for the changes in range conditions and lagged *PPC*. It is written as

$$(2) \quad \ln(PPC)_{it} = \beta_0 + \sum_{j=1}^{11} \beta_j D_{jit} + \beta_{12} MDP_{it} + \beta_{13} \ln(MFPR)_{i,t-1} + \beta_{14} \ln(PPC)_{i,t-1} + v_{it},$$

where $D_{jit} = 1$ if the observation occurs in the *j*th month, 0 otherwise. Preliminary estimation indicated the *DTP* variable was insignificant at the .2 level for a one-sided test so it was not included in the final model. This is not surprising since whole herds were eliminated as opposed to selective culling. The error v_{it} term is assumed to have the same properties as w_{it} al-

though v_{it} and w_{it} are not restricted to have equal variances.

By specifying *MFPR* to enter in lagged form to account for expectations used by farmers to adjust current production, both equations can be estimated without additionally estimating a demand model. Kaiser, Streeter, and Liu use a similar justification in estimating these supply equations separately from the demand equations in their model.

Swamy, Conway, and LeBlanc give a number of reasons the conventional fixed coefficient regression model may not be an accurate specification for econometric estimation. In a model with cross-sectional data, it can be argued that all the regression coefficients being identical is much more unlikely than having them vary from one cross-sectional entity to another. For the particular case at hand, the alternatives to dairying across states are quite varied as are climate and geography, so it is reasonable to expect coefficients to differ. As a result, the responses to various government programs are likely to be different. These reasons lead us to select a Swamy RCR as a plausible stochastic specification of the model. A fixed coefficient model for each state estimated as seemingly unrelated regressions is an alternative specification. It is rejected because it would not yield a mean response vector, which could be used for assessing program impacts for states not included in the sample.

The basic Swamy RCR specification is given as

$$(3) \quad y_i = x_i\beta_i + e_i \quad e_i \sim (0, \sigma_{ii}^2 I),$$

where y_i contains T observations on the dependent variable, x_i is a $T \times k$ matrix of observations on k explanatory variables, and e_i is a vector of T observations on the error terms. The β_i are the sum of the mean coefficient vector, β and a random disturbance vector, μ_i . Thus,

$$\beta_i = \beta + \mu_i \quad \mu_i \sim (0, \Delta).$$

Further, it is assumed that $E(\mu_i e_j) = 0$ for all i, j and that μ_i and μ_j are uncorrelated for all $i \neq j$. The mean coefficient vector, β , is estimated by generalized least squares (GLS). Since the matrix Δ is unknown, it must be estimated. The procedure recommended by Judge et al. (p. 542) is used.

In estimating the impact of the two programs, the econometric model gives more accurate simulations by using predictions of the coefficient vectors for each state instead of the mean vector

for all states. State coefficient vectors are computed using the best linear unbiased predictor (*BLUP*) as given in Judge et al. (p. 541). The formula for the prediction of the i th coefficient vector is given as

$$(4) \quad \hat{\beta}_i = \hat{\beta} + \Delta x_i' (x_i \Delta x_i' + \sigma_{ii} I)^{-1} (y_i - x_i \hat{\beta}),$$

where $\hat{\beta}$ is the GLS estimator of β . However, since Δ is unknown, the *BLUP*'s are estimated by substituting the estimate for Δ .

Data and Estimates

Data for *CN* and *PPC* come from various issues of the USDA publication *Milk Production*. The data for the blend price of milk and the feed price of 16% dairy ration are from various issues of *Agricultural Prices* (USDA). The blend price is by state by month. The feed prices are by state, by month from January 1983 through February 1986. After 1986 they are reported on a regional basis for January, April, July, and October. Monthly observations for the nonreported months are obtained by interpolation. Data for the MDP come from Miller and Carman and data for the DTP come from the Agricultural Conservation and Stabilization Service (personal communication). The twenty-one states in the sample produced 85% of the commercial milk in the United States from 1983 through 1988. About 78% of the base production diverted in the MDP was accounted for by the twenty-one states as well as 75% of the DTP-enrolled base. Hence, the sample is assumed to give an accurate representation of mean producer response in the United States.

Estimates of the two models are displayed in tables 1 and 2.¹ The signs of all the coefficients are consistent with expectations. Somewhat surprising are the high levels of the coefficients of determination for the models, particularly the *CN* equation. In a cross section such as this, considerable variation arises because cow numbers vary substantially across states. With a lagged dependent variable in the equation and lack of substantial variation in cow numbers from month to month within a state, it is not surprising that the coefficient of determination is high.

¹ The blend price of milk is gross price. Producers paid the \$.15/cwt. assessment and various deductions due to the price support program and Gramm-Rudman-Hollings. The model was estimated with these values netted out of blend price, but there was little change in the estimates of the mean coefficients.

^a The column under $\delta_{ii}^{1/2}$ is the estimated standard deviation of the *i*th coefficient, i.e., the square root of the *i*th diagonal element of the estimate of Δ .^b Single asterisk indicates significant at the 5% level of significance; double asterisk, significant at the 1% level of significance.

As mentioned earlier, an argument can be made that the *DTP* variable should maintain its value for those periods subsequent to the exit periods since those farmers exiting were precluded from engaging in dairying activity for five years after exiting. When *DTP* is so structured the percent root mean square error for the *CN* equation is 1.41, more than four times its value in table 1. In alternative specifications *MDP* in the post exit months was multiplied by d^r where d was varied from 0 to 1 and r was the number of months since the last exit month, 8/87. *PRMSE* was minimized, using a grid search, at $d = 0$. Thus, the conclusion must be that the mean behavior across states returned to the same behavioral relationships as before the *DTP*. Such behavior perhaps reflects those individuals not participating in the *DTP* expanding existing operations or new producers entering the dairy industry.

Two elasticities of supply can be computed from the model by multiplying the *CN* model by the *PPC* model to get total supply. The short-run supply elasticity is .0402, which is very inelastic. The long-run elasticity is .750, which is somewhat higher than those reported in other studies. Wilson and Thompson found an approximate long-term elasticity of .521, which is also close to the elasticities found by Halvorson for two of his five models. However, both of these studies used only time-series data which could lead to smaller estimates than ours. The elasticity estimates in the present study are sensitive to the fact that the coefficient of the lagged dependent variable is nearly one in the *CN* equation. With a monthly equation for cow numbers, it is not surprising that this parameter would be near to one since herd sizes do not vary much from month to month.

^a The column under $\delta_{ii}^{1/2}$ is the estimated standard deviation of the *i*th coefficient, i.e., the square root of the *i*th diagonal element of the estimate of Δ .^b Single asterisk indicates significant at 5% level; double asterisk, significant at 1% level.

As a further test of the equations' accuracy, the monthly production in each state was simulated over the sample period. The observed values of the dependent variables were used for the lagged dependent variables. Total production was simulated with percent root mean square errors (*PRMSE*) ranging from 4.05 to 1.03 with eighteen of the twenty-one states below 2.0. The *PRMSE* for monthly production aggregated over the twenty-one states was .834. Because the policy simulations use predicted values of the endogenous variables over observations from 2/83–6/88, it is useful to consider the *PRMSE*'s for the model using predicted values of the lagged endogenous variables. Over these sixty-five observations the *PRMSE*'s ranged from 6.74 to 2.03. For the aggregate amount the *PRMSE* is 2.11.

The policy variables also have the expected signs and all are statistically significant at the .05 level. Because of the double logarithmic specification the coefficients can be viewed as elasticities of reductions per month. Thus, the MDP had a short-run elasticity of .0351 per month during the program and DTP has a short-run elasticity of $-.0206$. However, because the coefficients in tables 1 and 2 are means of the various coefficients across states, they are not necessarily reflective of the aggregate effect of changes in independent variables since the population levels in the various states differ. This effect is illustrated later in the policy simulations.

The last columns in tables 1 and 2 give the estimated standard deviations of the coefficients for their variation over states. Using the BLUP's as computed from (4), the coefficient of MDP in the *CN* equation ranged from $-.0303$ to $.0042$. In the *PPC* equation the coefficient of MDP ranged from $-.0904$ to $.0035$. The coefficient of DTP ranged from $-.0364$ to $-.0075$. Clearly, these rates have different short-term implications. However, it is more important to analyze the dynamic implications of the programs. In particular, the corresponding variations of the coefficients of the lagged dependent variables have a major influence on the overall impact of a policy in a particular state. The state-by-state variations in impact are considered in the simulation section.

As a final test of the model's usefulness, the last six months of 1988, which were not included in the estimation sample, were simulated. In this simulation the predicted values of the lagged endogenous variables were used instead of the observed values for every month but

July 1988, which used the observed values in June 1988. The *PRMSE*'s for total production ranged from 12.6 to 1.75 with a mean of 5.72. For the monthly aggregate production over twenty-one states for six months, the *PRMSE* was 5.69%. Given the various measures of goodness of fit, the model is considered useful for policy analysis.

Simulations and Policy Analysis

Because of the dynamic nature of the model, interpreting the coefficients of the binary variables as representing the impact of the policies can be misleading. To avoid this, the model was simulated four different ways from February 1983 through June 1988. In the base simulation it was assumed that both of the programs were in effect. Then the model was simulated assuming that only the MDP was in effect, then only the DTP, and then with neither program in effect. The impact of the programs can be estimated by comparing the production levels in the simulations with the policy variables at nonzero levels with production levels assuming no programs. Comparisons are made on an aggregate level as well as state by state. This latter comparison is important to measure the heterogeneity of state responses to per hundredweight participation in the programs.

In the policy simulations deleting one or both of the programs, blend prices are assumed to be endogenous with feed prices at their observed levels. The endogenous blend prices are computed in the following way. Recall that milk output levels in period t are determined as a function of prices lagged one period. The production levels in period t with and without the program(s) are computed. It is assumed that all additional production due to absence of a program(s) would be used in manufacturing grade.² Thus, the blend price is changed by computing the new proportions of fluid milk and nonfluid milk. This new blend price becomes the price used in the next period.

Subtracting production in the base simulation from the third simulation gives the impact of both of the programs taken together. These figures are shown under the column "COMBINE" in table 3. For the twenty-one states, the

² Manufacturing grade is used instead of Class II because a consistent Class II price by state is not available. In states where manufacturing prices are not available, Class III prices for milk market order districts were used.

^a MDP denotes milk reduction due to MDP only (assumes DTP was not implemented).

^b Amount of base production enrolled for diversion into MDP, 15-month basis (Miller and Carman)

^c DTP denotes milk reduction due to DTP only (assume MDP was not implemented)

^d COMBINE denotes milk reduction due to both MDP and DTP.

^e Margin denotes the marginal impact of the DTP in addition to MDP. Computed as COMBINE less MDP.

^f Amount of annual base production by herds liquidated in DTP (ASCS, personal communication).

two programs resulted in a cumulative reduction of milk production of 23 billion pounds through June of 1988. Of this the MDP generated 10.32 billion pounds.

It would be somewhat misleading to say that the DTP resulted in a cumulative 12.83 billion pound decrease through June 1988 because the column under DTP assumes that the DTP was implemented without the MDP. The marginal contribution of the DTP is 12.68 billion because of when it followed the MDP. The fifth column in table 3 is computed as the values of the fourth column less the corresponding values of the first column. There is a 1.1% decrease in the reductions resulting from the DTP because of when it was implemented relative to the MDP. Presumably, if the DTP had begun sooner after the conclusion of the MDP, the DTP's impact would have been even less.

Long- and short-term aspects of the two programs are clear from figure 1. Twelve months after the cessation of the MDP, production levels had recovered almost half of the reduction due to the MDP. However, the impact of the DTP was greater than the MDP on a percentage of total output basis and the rate of recovery from

the DTP was slower than from the MDP. Hence the DTP appears to have longer-term effects than the MDP.

Effectiveness of the programs varied by state. Participation rates varied for both programs by state and so did diminution of production per pound of base production enrolled. Columns 2 and 6 in table 3 show the amount of production enrolled. Dividing column 1 by 2 and column 5 by 6 gives the ratios of production declines to base enrolled. For the MDP these ranged from 4.16 for Michigan to -.2 for Wisconsin. The ratio for all twenty-one states combined was 1.42. For the DTP the ratios ranged from 3.88 (Wisconsin) to .503 (Idaho). The ratio for the twenty-one states combined was 1.48. However, these figures account for reductions only through June 1988. The DTP ratios will increase as the impact of the DTP is felt beyond June 1988.

Concluding Comment

Swamy random coefficient regression equations with cow numbers and production per cow as dependent variables were estimated using a time

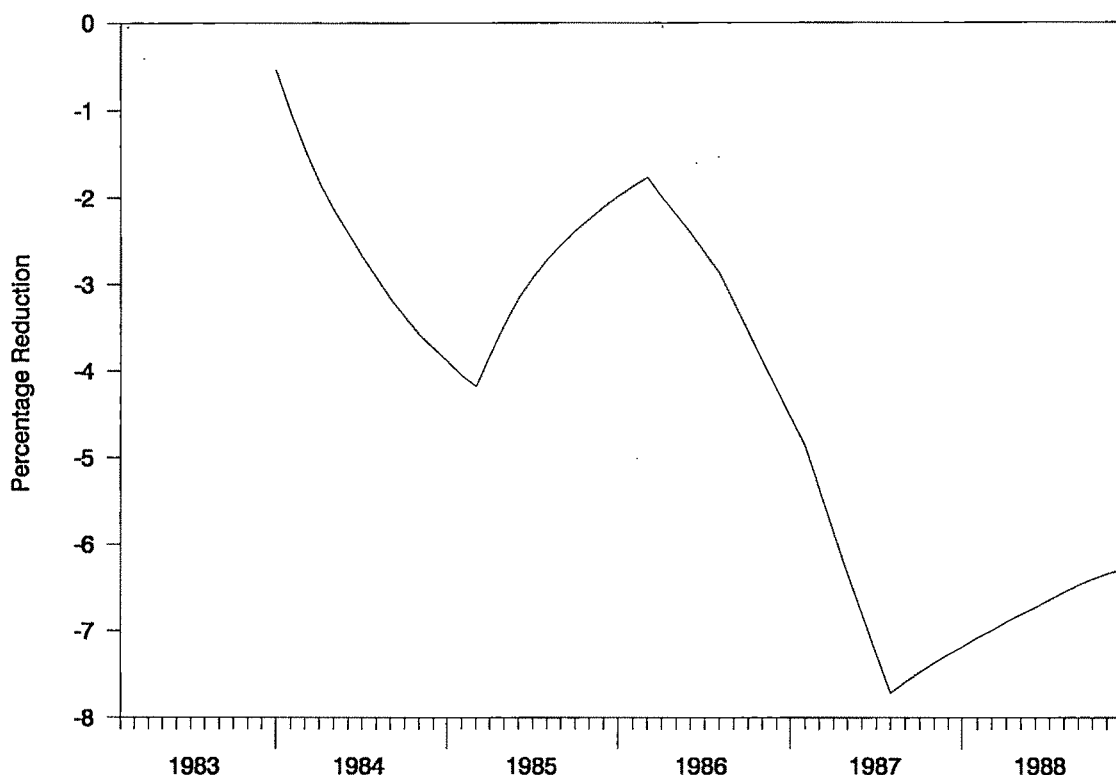

Figure 1. Percentage reduction in milk production due to DTP and MDP, 21 states

series of cross-sectional data on twenty-one major milk-producing states in the United States. These equations were used to estimate the impact of two very different programs that were implemented in the mid-1980s to reduce surplus commercial milk production. The first program was the milk diversion program which had a short-term impact. Within a year after its cessation, production had nearly recovered half of the decrease induced by the MDP. On the other hand, the whole herd buyout ceased in August 1987, but the rate of recovery to previous levels was slower. Hence, the dairy termination program has had a longer-term impact than the milk diversion program. However, the five-year ban on production by producers exiting under the DTP appears to have had little, if any, effect. Herd size began increasing immediately after the last exit month to pre-DTP equilibrium levels.

The effect of the programs was not uniform across the states. This is indicated by variations in coefficients across states as well as by the impacts per unit of base enrolled in the two programs. An explanation for this variation is that in some states the demand for milk was probably sufficiently strong that nonparticipating

producers increased production substantially. For future dairy supply management programs, an important implication is that the same program could have very different regional impacts, perhaps requiring coordination to obtain desired effects.

Determinants of Agricultural Economics Faculty Retirement

Josef M. Broder, Fred C. White, and Teresa D. Taylor

The retirement experiences of faculty who had retired from 1862 land grant universities are described. Health, financial, family, and professional characteristics of early retirees are contrasted to those of late retirees. Determinants of faculty retirement are identified in the context of a general retirement model. Model results indicate that years-of-service to retirement programs, number of children, mental health, health trends, age at initial employment, and faculty-spouse age differences are positively related to retirement age. Salary levels, net worth, and extension appointments are inversely related to retirement age. Implications of recent changes in the agricultural economics profession on expected retirement behavior are discussed.

Key words: faculty compensation, faculty retirement, professional affairs, retirement profiles.

The typical agricultural economist pursues a productive career for thirty to forty years and then leaves the profession through retirement. Given life expectancies that exceed eligible retirement age, most of our profession will join the ranks of the retired. Among the major life-cycle decisions made by agricultural economists, few are as difficult as the decision to retire. Despite the inevitability of retirement, little is known about retired agricultural economists. While the retirement literature offers some insights into the retirement experience of university faculty, the mission and appointment structure of agricultural economics faculty are unique and worthy of separate analysis.

In response to this absence of information on retired agricultural economists, a survey of agricultural economics faculty who had retired from 1862 land grant universities was conducted. The purpose of the survey was to develop personal profiles of retired agricultural economists and to gain a better understanding of the decision to retire. The objectives of this paper are (a) to describe biographical characteristics of retired faculty, (b) to describe the health and financial pro-

files of retired faculty, and (c) to identify factors that influenced the decision to retire.

The agricultural economics profession has maintained an ongoing interest in professional affairs. Recent studies have examined rankings of individual departments (Beilock, Polopolous, and Correal), assessments of journals used by agricultural economists (Broder and Ziemer 1985), the journal publication process (Brorsen), productivity of agricultural economics faculty (Broder and Ziemer 1982), undergraduate student affairs (Litzenberg and Schneider, Erven), extension-related issues (McDowell; Knight, Johnson, and Finley) and professional interests (Pope and Hallam). These publications offer useful insights into the life cycle of our profession. Largely excluded from this literature are studies on the retirement experiences of faculty. In their absence, the life-cycle assessment of the profession would be incomplete.

Current Study

Data for the current study were taken from a survey of retired agricultural economics faculty at 1862 land grant universities, conducted in the spring of 1988. Department heads at forty-eight 1862 land grant universities were asked to provide names and addresses of living faculty who had retired from their departments. The 404 names received from 42 of the department heads responding to the request were used as the sur-

Josef M. Broder, Fred C. White, and Teresa D. Taylor are professors, Department of Agricultural Economics, University of Georgia, and an agricultural economist, Tennessee Valley Authority.

The authors would like to thank Joseph P. Walsh, Jr., of the Social Security Administration, and Marc A. Eason, Agricultural Business Office, University of Georgia, for their many useful comments on this paper.

vey population and were mailed questionnaires. Two hundred nine (209) usable responses were received for a response rate of 51.7%.

Respondent Characteristics

Respondents were asked to describe their professional activities and biographical status at the time of retirement (table 1). These characteristics were used to develop profiles of early and late retirees. First, working definitions of early and late retirement were developed for this analysis. Second, mean differences between a particular retiree group and all other groups were tested using Student's *t*-statistic.

While definitions of early and late retirement are related to particular retirement systems, the literature draws a clear distinction between early and late retirees with the normal age of retirement at 65 (Bazzali). Because the average retirement age of agricultural economics faculty was 63, with 71% retiring before age 66, this

delineation was deemed too restrictive for this study. To account for the earlier retirement age of agricultural economics faculty and the flexibility of many faculty retirement programs, the period of normal retirement was expanded to include ages 62 through 65. As in previous studies, respondents retiring after age 65 were described as having retired late. Respondents retiring before age 62 were described as having retired early. This definition of early retirement is consistent with years of eligibility for retirement benefits as defined by the Social Security Administration. Persons fully insured under Social Security can retire as early as age 62 with permanent reductions in retirement benefits or at age 65 with full benefits (U.S. Department of Health and Human Services). Approximately 77% of respondents had made contributions to Social Security and were eligible for Social Security benefits.

Respondents were asked to indicate their faculty appointments at retirement. About half of the respondents had multiple appointments. Ex-

^a Percent of respondents with appointments.

tension appointments were most frequent among respondents, followed by teaching and research. The early retirement group was dominated by extension faculty with over two-thirds of this group having extension appointments. The late retirement group was dominated by faculty with teaching appointments, followed by faculty with research appointments. These data suggest that teaching and research faculty tended to retire later than their extension counterparts. Financial considerations were cited as the major reason for retirement among early retirees, while health reasons dominated those in the normal age of retirement. As expected, mandatory retirement was most common among late retirees.

The proportion of respondents with extension appointments was found to be higher than in the working population of agricultural economics faculty (Broder and Ziemer 1982, 1985). These differences were attributed to the research design and appointment-related differences in retirement age. Because extension faculty tended to retire early, the percentage of retired faculty with former extension appointments should exceed the percentage of extension faculty among the working population of agricultural economics faculty. Although no systematic tests were

made to identify response bias, the sample population was thought to represent the population of retired agricultural economics faculty.

Retirement Profiles

Retirement profiles of respondents are shown in table 2. The average years of birth for the early, normal, and late respondent groups were 1923, 1917, and 1912, respectively. Age differences between respondent and spouse appeared to increase with retirement age from 2.5 years for early retirees to 4.0 for late retirees. No significant differences were found in the percentage of spouses employed at the time of the respondent's retirement. However, early retirees tended to retire before their spouses' retirement, while late retirees tended to work beyond their spouses' retirement. The fewest children were reported by late retirees, while early retirees reported having the largest number of persons living in the current household.

Respondents who retired early reported having the fewest years of service in university retirement programs and the most years in federal retirement. Late retirees reported just the op-

Federal retirement	0.7	0.6	0.3
Other programs	3.7	1.0***	3.8

^a Means different at alpha levels = 0.01 (***), 0.05 (**), and 0.10 (*).

^b The percentage of respondents contributing to individual retirement programs were: university 76.6%, Social Security 76.6%, federal 53.1%, and other 32.0%.

posite. These data suggest that for the survey population, retirement age appears to be inversely related to years of service in federal retirement programs and directly related to years of service in university retirement programs. Spouses had more years of service in Social Security than in all other retirement programs combined.

Health Profiles

Previous studies have shown health to be a primary determinant in the decision to retire (Anderson and Burkhauser). The sources of health data used in the literature include self-reported health and health based on mortality experience. The current study attempted to measure self-reported health in a cross-sectional framework. Self-reported health data were obtained by asking respondents to rate their physical health and mental well-being before and after retirement. Respondent ratings were based on a seven-point scale with a value of 7 = excellent, a value of 4 = average, and a value of 1 = poor.

Self-reported health data are shown in table 3, including (a) the average health for the 1970–88 period, (b) the change in health during the

1970–88 period, and (c) health at retirement. The lowest average levels of physical and mental health were reported by respondents who retired early. Retirees from all categories reported that their physical health had declined during the study period. The mental health of all but the late retirement group had improved during the study period. Significantly higher levels of mental health at retirement were reported by late retirees. The lowest levels of physical and mental health at retirement were reported by early retirees.

To learn more about changes in self-reported health, respondents were asked to list special reasons for changes in their physical and mental health. Early retirees reported stress as the most frequent physical ailment, followed by cardiovascular, and a variety of other disorders. Early retirees cited mental stress and declining physical health as major reasons for changes in mental well-being.

Two-thirds of late retirees gave no specific reasons for changes in their physical health. Among reasons given by this group were cardiovascular and other physical health problems. Declining physical health and mental stress were cited by late retirees as major reasons for changes in mental health. When contrasted to early re-

tierees, late retirees reported having fewer physical and mental health problems.

Since health was thought to influence the decision to retire, health indexes were also presented by respondent age. Self-reported health, shown in figure 1, suggests that mental and physical health of respondents were similar through age 55 and diverged afterwards. After age 55, respondents reported mental health as being superior to physical health with the greatest divergence occurring at ages 70 to 75. Conversely, the variation in reported physical health was greater than that for mental health with the greatest divergence also occurring at ages 70 to

75. Discrepancies between mental and physical health suggest that physical health alone may not be a reliable indicator of respondent well-being or predictor of faculty retirement.

Financial Profiles

Previous studies have shown that the financial status of workers has a significant influence on their decision to retire (Fields and Mitchell). Hence, respondents were asked to report retirement incomes, expenses, and net worth. Financial profiles of retirees are shown in table 4.

^a Means different at alpha levels = 0.01 (***), 0.05 (**), and 0.10 (*).

^b Percentages of respondent groups with 20 or more hours of compensated professional activities were early 12.6%, normal 4.0%, and late 5.0%.

Significant differences were found among salaries earned by spouses during the respondent's last year of employment. Spouses of early retirees earned significantly more than spouses of later retirees.

Respondents were asked to report their net worths in two categories: home and other investments. The largest net worth in home was reported by late retirees, while the largest net worth in other investments was reported by early retirees. However, differences in net worths were not statistically significant. No significant differences were found in the annual incomes received from all pensions held by the respondent and spouse.

Early retirees reported earning \$55,066 in their last year of employment, adjusted to 1988 dollars by the consumer price index. The spouse's salary at the time of the respondent's retirement was reported to be \$10,454 in 1988 dollars. Thus, combined earnings of early retirees and their spouses were \$65,520. When these combined preretirement earnings were compared to total postretirement income (pensions and other

sources) of \$60,863, the gross earnings of early retirees decreased by 7.1% after retirement. By contrast, gross earnings of normal and late retirees increased 7.4%, and 10.6%, respectively, after retirement. These data suggest that monetary costs of retirement appear to decline with retirement age.

These financial data also suggest that postretirement incomes from nonpension sources are important. These findings are consistent with respondents' assessment of how well their retirement incomes have kept pace with their cost of living. Despite observed postretirement reductions in gross earnings, early retirees indicated that the growth in their retirement income had exceeded cost-of-living increases by 1.7%. Comparable growth patterns were reported by late retirees, while retirees in the normal group reported smaller gains in real income after retirement. This growth in postretirement income was attributed to cost-of-living adjustments in Social Security payments as shown in table 2 and asset disinvestment strategies of retirees as shown by declining net worths in figure 2. Some

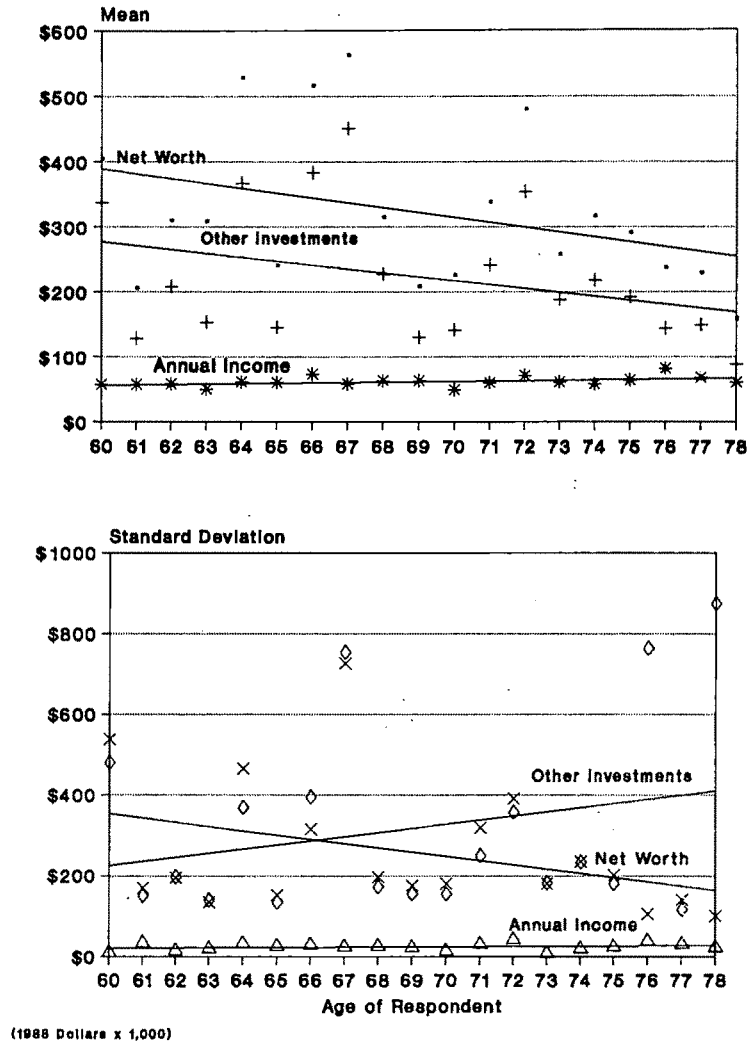

Figure 2. Financial profiles of retired agricultural economics faculty

of this growth in retirement income was also attributed to income from professional activities. Early, normal, and late retirees reported spending 7.7, 4.6, and 3.3 hours per week, respectively, on compensated professional activities.

A comparison of financial profiles by age of respondent is shown in figure 2. Linear trends of mean retiree incomes and net worth reveal constant incomes and gradual declines in net worths. Given that home values and annual income streams remain constant, retirees appear to be disinvesting other investments to maintain their annual incomes. These data suggest that financial profiles of retired faculty are likely to be affected by the length of the anticipated retirement period. Lengthy retirement periods would necessitate greater net worths and disin-

vestment over a longer time frame. Respondents anticipating longer retirement periods were more likely to purchase life insurance to maximize the value of their pensions and provide financial security for their spouses. Lengthy retirement periods were also associated with declines in the variability of total net worth and increases in the variability in other investments.

Retirement Model

Relationships among retiree health, finances, and biographical characteristics, and retirement age were examined in a general retirement model. The purpose of this retirement model was to identify and estimate determinants of retire-

ment. The conceptual framework upon which the model was developed assumes that faculty maximize utility subject to various monetary and nonmonetary constraints. Faculty derive utility from combinations of work and leisure, subject to the constraints imposed by income, health, and family obligations. The relative prices of work and leisure determine the number of hours the respondent works each period. Likewise, the relative prices or opportunity costs of pre- and post-retirement influence faculty retirement decisions, subject to institutional and market constraints.

Work and leisure are assumed to be imperfect substitutes in consumption, suggesting that retirement is a rational alternative to the faculty's career. Imperfect substitution between these activities suggest that the transition to retirement is apt to be gradual, with the faculty member working fewer hours near retirement and maintaining some professional activities after retirement (Honig and Hanoch).

The decision to retire is based on the faculty member's expected capacity to enjoy retirement. Financial assets are assumed to enhance the utility derived from retirement, while poor health diminishes the ability to work or to derive utility from retirement. Family relationships can either enhance or diminish the relative utility from retirement. Family members can offer financial and personal support to retirees and make their retirement experience more enjoyable. Finally, the structure of retirement programs affects the relative costs and, thus, the age of retirement.

The faculty member's age at retirement was used as the dependent variable in an econometric model to explain retirement behavior among agricultural economics faculty. Explanatory variables suggested by the conceptual framework and previous research are as follows.

End-of-career financial profiles have been found to influence the decision to retire (Anderson and Burkhauser, Fields and Mitchell, Honig and Hanoch, Bazzali). For this study, five variables were used to describe financial profiles of respondents. Respondent's salary during last year of employment (*RSAL*) was entered in 1988 dollars as a measure of the opportunity cost of retirement and the potential earnings from university pensions. The inclusion of *RSAL* assumed that faculty retirement follows the attainment of a threshold level of postretirement income. Higher salaries are assumed to provide greater financial security during retirement. Because pensions are generally based on earnings before retirement, an inverse relationship was

expected between retirement age and respondent earnings, indicating higher salaries contribute to earlier retirement.

Because almost 90% of respondents were married, spousal earnings were also expected to influence the decision to retire. The annual salary earned by the respondent's spouse during the respondent's last year of employment (*SSAL*) was entered into the model in 1988 dollars and was expected to have a negative influence on retirement age. With few exceptions, retired faculty members had contributed to several retirement programs. Hence, the decision to retire was hypothesized to be based on contributions made by respondent and spouse to all retirement programs. Years of service to all retirement programs (*TOTSER*) were entered into the model on the assumption that contributions to retirement programs enhance the financial security of the retired household. The variable *years of service* was expected to have a positive impact on retirement age.

Other sources of retirement income were also hypothesized as important determinants of retirement. Of the financial assets owned by faculty, net worth in non-home investments was considered the more liquid and amenable to disinvestment. Disinvestments of non-home assets provide income to supplement employer pensions and increase financial security during retirement. Thus, non-home assets were entered into the model (*INVEST*) and expected to have a negative impact on retirement age.

Children serve as a potential source of financial and psychological support during retirement. Retirement also affords the satisfaction of spending leisure time with children and grandchildren. Thus, the number of children was entered into the model and expected to have a negative impact on retirement age.

Previous research has shown health is a primary determinant of retirement (Anderson and Burkhauser, Bazzali). This study hypothesized that respondent attitude and assessments about health just before retirement were instrumental in the retirement decision. Thus, self-reported mental health before retirement (*MENTAL*) was entered into the model and expected to have a positive impact on retirement age. Faculty who gave high ratings to their mental well-being during employment were expected to retire later.

Previous research has shown that morbidity rates have an influence on the retirement decision (Anderson and Burkhauser). Lacking life expectancy data on individual respondents, the year of retirement (*TREND*) was entered into the

model as a proxy for increases in general health care and life expectancies that have occurred during the study period. The availability of improved health care and greater life expectancies were hypothesized to have a positive impact on retirement age.

The final set of explanatory variables were included to account for and, thus, control for situational differences in retirement programs and age differences between respondent and spouse (Dorfman). The diversity of retirement programs across universities precluded systematic classification and testing of program differences. However, the observed differences in retirements by faculty appointments suggested that faculty with extension appointments tended to retire earlier than their counterparts in teaching and research. The percentage of the respondent's appointment designated as extension (*SER*) was entered into the model and expected to be inversely related to retirement age. Reasons for early retirement among extension faculty were attributed to the more generous retirement benefits and options available to extension faculty under the pre-1983 Civil Service Retirement System (CSRS). Under this system, extension faculty with 30, 20, and 5 years of service, respectively, could retire at ages 55, 60, and 62 without penalty (U.S. Office of Personnel Management). Faculty under CSRS were also exempt from Social Security taxes and were not subject to the more restrictive eligibility criteria for Social Security benefits (U.S. Department of Health and Human Services). With an average of 25.6 years of service to the Civil Service Retirement, many extension faculty were eligible to retire before age 62. The tendency for research and teaching faculty to retire later was attributed to more restrictive retirement benefits among university retirement programs (Eason).

Other factors associated with early retirement among extension faculty include greater job-related stress and greater opportunities for consulting. In cross-tabulations of faculty by majority appointment (>50%), the percentage of extension faculty reporting physical and mental stress was 13% and 28%, respectively. These levels were twice that reported by other faculty. Extension faculty also reported an average of 6.7 hours of compensated professional activities after retirement as compared with 4.4 hours reported by other faculty.

The value of a university retirement program is considerably enhanced once an employee becomes vested. Once vested, the value of the pension is increased substantially by matching

funds provided by the employer. Vesting often requires that an employee make contributions to a retirement program for a minimum number of years. The value of a pension, also depends on the total years of service. For example, thirty years of service are required by some programs to be eligible for full pension benefits. Both of these retirement program attributes are sensitive to the age of initial employment with the university. The younger one begins employment, the sooner these program requirements can be met and the sooner full benefits can be received at retirement. Thus, the respondent's age at initial employment with the university (*AGEURP*) was entered in the model and expected to have a positive impact on retirement age.

Retirement programs also differ in their policies on mandatory retirement. To capture these differences across respondents, a binary variable for mandatory retirement (*MAND*) was entered (Leigh). *MAND* was equal to one if the respondent retirement was mandatory, zero otherwise.

Finally, age differences between respondent and spouse were also thought to affect the retirement decision. Because retirement affords the individual or household an opportunity to travel and relocate, the respondent's decision to retire was hypothesized to be closely related to the spouse's decision to retire. Age differences between respondent and spouse (*AGEDIFF*) were entered into the model with the expectation that respondents with younger spouses tended to postpone retirement to accommodate their spouses' working career.

Results

Ordinary least squares estimates of the retirement model are shown in table 5. With one exception, all estimated parameters were significant and consistent with a priori expectations. The empirical model found that total service to all retirement programs, self-reported mental health, health care trends, age at initial employment with the university, mandatory retirement, and age differences between respondent and spouse were positively related to retirement age. End-of-career salaries, net worth in non-home investments, number of children, and extension appointments were inversely related to retirement age. The lack of significance with the net worth variable was attributed to suspected inconsistencies among respondents in reporting the value of pensions as non-home assets. Model

estimates lend support to the utility maximization framework of the retirement decision.

The implications of model estimates must be interpreted in relation to the magnitude of their impacts on retirement age. For example, faculty with 100% extension appointments tended to retire three years earlier than teaching and research faculty with no extension appointments. Each child hastened the retirement decision by four months. In successive years of the survey period, the average age at retirement increased by five weeks. An additional \$10,000 in household income hastened the retirement decision by six months. Faculty elected to retire 3.7 years before mandatory retirement.

Conclusions

The findings of this paper suggest that the decision to retire is complex and not based on any single criterion. Although many determinants of

retirement were identified, the impacts of many of these determinants are small in isolation. These findings of this study have implications for the inevitability of retirement and relatively narrow time frame during which the retirement decision is made. The inevitability of retirement should alert faculty and universities to take active roles in planning for retirement, both mentally and financially (Dorfman).

The inability to obtain a comprehensive mailing list of retired agricultural economics faculty from our professional directories has implications for our professional associations. The willingness of retired faculty to spend time on professional activities suggest that professional associations have failed to fully utilize the human capital embodied in many of our retired colleagues. A restructuring of professional association dues and activities to encourage greater participation by retired faculty is worthy of consideration.

The extent to which the findings of this re-

search can be generalized merits discussion. First, the survey population was limited to agricultural economics faculty who had retired from land grant universities. Agricultural economists who had retired from government and private industry were not examined in the survey and, hence, model parameters may not be applicable to these groups. Second, the age of the respondent population enabled many extension faculty to be eligible for the pre-1983 Civil Service Retirement Program. Social Security Amendments of 1983 mandated Social Security coverage for all new federal employees hired after 1983 (Cowen et al.). This provision led to the creation of the Federal Employees' Retirement System (FERS). With retirement benefits under FERS coordinated with Social Security coverage, many of the generous retirement provisions previously available to CSRS participants have been eliminated along with incentives for early retirement. Hence, model parameters may not be valid for extension faculty under the revised FERS.

Other changes taking place in the agricultural economics profession may also change individual retirement strategies. Among these are faculty retrenchment, the changing pattern of twelve-month appointments, changes in the mission of agricultural economics departments, and the consolidation of teaching and research programs on a regional setting. Changes which result in a general decline in the demand for agricultural economics faculty might advance programs for early retirement and result in a reduction in the average retirement age of agricultural economics faculty. By contrast, the abandonment or liberalization of mandatory retirement laws might delay the retirement decision of some faculty, but their impacts on increasing the average age of retirement are expected to be small.

Local Economic Conditions and Wage Labor Decisions of Farm and Rural Nonfarm Couples

J. G. Tokle and Wallace E. Huffman

Effects of geographical differences in local economic conditions on wage labor demand and wage labor participation decisions of rural couples are examined for Current Population Survey households 1978–82. Wage premiums are shown to exist for localities anticipating labor demand growth, higher unemployment rates, larger share of employment in services, and higher costs of living. These effects are stronger for males than females. Effects of local economic conditions on the probability of wage work are consistent with expected market wage and reservation wage effects, and for farm households the probability of wage work increases when expected farm output prices decline or the wage increases.

Key words: farm couples, human capital, local business cycles, local labor markets, rural, wage labor participation, wage rates.

The objective of this paper is to examine the effects of geographical differences in local economic conditions on wage labor demand and labor force participation decisions of U.S. farm and rural nonfarm couples. One hypothesis is that localities with higher anticipated employment growth and unemployment rates pay a wage premium to attract workers from other localities. Thus, when the local anticipated employment growth rate declines (relative to the national rate) real wage rates fall in these localities and rise in others. Another hypothesis is that localities experiencing unanticipated negative labor market shocks show a decline of real wage rates; an example is the case of the upper Midwest during 1981–82. Other geographical wage differences are the result of cost of living and locational amenities.

A considerable amount of research on labor supply of married males and females has utilized a single-worker model (DaVanzo, DeTray, and Greenberg; Mroz, table 1). Furthermore, Mroz has continued this tradition in a

recent analysis of the sensitivity of female labor supply to an array of economic and statistical assumptions. However, we believe that new insights can be gained by considering labor supply decisions in a two-worker, husband-wife model, e.g., see Huffman and Lange. In particular, a spouse's wage has substitution and income effects rather than just income effects alone. A spouse's education may affect a partner's labor supply decision by changing the reservation wage through efficiency effects on family wealth and household production (and for farm households on farm production) or taste. A couple's labor supply decisions are affected by the same economic shocks, so a joint estimation procedure should increase the statistical efficiency of the parameter estimates.

The paper has the following organization: The empirical setting for the study is presented first. Second, the economic models of labor demand and labor supply are developed, including local labor market effects. Third, the data and econometric model are summarized. Fourth, the econometric results are reported. Finally, some conclusions and implications are presented.

The Empirical Setting

This section presents summary measures of differences across localities in labor market char-

The authors are, respectively, an assistant professor, Idaho State University, and a professor, Iowa State University.

Journal Paper No. J-14190 of the Iowa Agriculture and Home Economics Experiment Station Project No. 2738.

Financial assistance was provided by a grant from the Ford Foundation through the Aspen Institute and by the Iowa Agriculture and Home Economics Experiment Station.

Helpful comments were obtained from two anonymous referees, Peter Orazem, and Helen Jensen. Perry Warjiyo provided valuable research assistance in refitting the models.

acteristics, primarily unemployment rates, employment growth, and shocks to labor demand. The basic geographic unit is a state because states are the smallest unit for which annual data are available. Statistics are reported for the twenty-three states having the largest rural population in 1980.

Equilibrium unemployment rates differ geographically and have not tended to converge over time. Table 1 presents the ratio of predicted state unemployment rates to the predicted national unemployment rate for 1970, 1974, 1978, and 1982.¹ Only four years are reported for each state to conserve space; these years lead up to and include the 1978–82 period covered in this study. At any point in time important regional differ-

ences in unemployment rates exist and tend to persist over time (e.g., Hall, Abowd and Ashenfelter, Adams, Topel). For example, the unemployment rates are uniformly higher than average for Michigan, West Virginia, Mississippi, and Louisiana. The unemployment rates are uniformly below average for Pennsylvania, Minnesota, Iowa, Virginia, North Carolina, Georgia, and Texas. For other states, no simple relationship exists during 1970–82 between their unemployment rate and the national average rate.

Table 1 also presents the ratio of predicted state employment growth rates to the predicted national employment growth rate.² The table shows that the employment growth rates in Georgia, Florida, Louisiana, Texas, and Cali-

¹ Each state's annual unemployment rate, 1968–82, and the national unemployment rate were regressed on quadratic trend. The predicted unemployment rates are forecasts from these regressions.

² The natural logarithm of total private sector employment, 1968–82, was regressed on quadratic trend. Predicted employment growth rates are the first differences of the predicted employment values from these regressions.

Table 1. Geographical Distribution of Unemployment and Employment, Twenty-three Selected States, 1970–82

States	Unemployment ^a				Employment ^b				Rural population 1980 (1,000)

^a Numbers are ratios of the predicted state unemployment rate to the predicted national unemployment rate. Annual unemployment rates for each state and for the U.S. were regressed on quadratic trend, 1968–82, to obtain the predictions.

^b Numbers are ratios of the predicted state employment growth rate to the predicted national employment growth rate. The logarithm of annual employment in the private sector for each state and the U.S. were regressed on quadratic trend, 1968–82. The predicted employment growth is the difference between the predicted logarithm of employment in two adjacent years.

ifornia are uniformly larger than average, and for New York, Pennsylvania, Ohio, Illinois, and Missouri, employment growth is uniformly below the national average. During this period, some states (i.e., Iowa, West Virginia, South Carolina, Kentucky, Tennessee, Alabama, and Mississippi) went from having far above- to far below-average employment growth rates. In general, these data show a very unequal geographical distribution of employment growth 1970–82.

The geographical distribution of labor demand “shocks” is also unequal. Table 2 presents indexes of local labor demand shocks for the subperiod 1978–82. These measures were constructed as follows. First, the natural logarithm of annual private employment (1968–82) was regressed on quadratic trend. The residuals from these regressions, ϵ_t^s , are indexes of time-varying local demand conditions in state s and year t . Second, the natural logarithm of the national aggregate employment was regressed on quadratic trend. The residuals from this regression, ϵ_t , measure the aggregate labor demand

disturbance in year t . Relative local labor demand disturbances in year t and state s are then defined as $\eta_t^s = \epsilon_t^s - \epsilon_t$, which expresses the current local labor demand “shock” as a deviation from the aggregate labor demand “shock.” (This measure is used by Topel, p. S129).

These measures of local labor demand disturbances have two important features. First, for a given year, substantial geographical variation in employment disturbances occurs. They also are largely unrelated to the aggregate business cycle. Second, for a given state the successive disturbances occur as local cycles. Shocks with the same sign tend to persist for a couple of years then to reverse themselves.

When workers and firms are immobile, local economic conditions will affect real wage rates. Although workers are largely immobile in the short run, they are geographically mobile in the long run. However, differences among localities in their net advantages to firms (industries) and in their amenities and cost of living characteristics to workers contribute to permanent differences in labor markets of different localities.

Table 2. Relative Employment Disturbance, Twenty-three Selected States, 1978–82

United States	2.39	3.59	1.88	0.34	-3.77

Note: The numbers are measures of $\eta_t^s = \epsilon_t^s - \epsilon_t$, except for the last row. See the text for details.

The Economic Model

In a labor market workers simultaneously sell their services and buy the attributes of jobs, including location. Employers also buy the services and characteristics of workers and sell job attributes. Therefore, the theory of equalizing wage differentials stresses both supply and demand for labor, and the market equilibrium process allocates or assigns specific workers to specific firms and locations (Rosen).

Labor Demand

The actual wage can be viewed as the summation of two distinct transactions, one for labor services and worker characteristics and another for job and locational attributes (Rosen). Localities are assumed heterogeneous over characteristics that matter for optimal firm-industry (employer) and household (worker) decisions. This environment contains spatially related competitive labor markets with equilibrium wage differentials. A wage premium is paid by employers to induce workers to undertake undesirable tasks or work at an undesirable location. Unequal transitory shocks to labor demand in different localities are an added source of geographical differences in wage rates.

The wage elasticity of aggregate labor demand for a locality is negative, but individuals face a perfectly elastic demand for their labor. Our labor demand or wage rates at a given location and for a given sex are assumed to depend on skill or human capital (ζ) and job or locational characteristics—permanent or anticipated labor market conditions (Ω), transitory or unanticipated labor market conditions (ω), local cost of living (ψ), and locational amenities (Δ). This relationship is summarized as

$$(1) \quad W^j = W^j(\zeta^j, \Omega, \omega, \psi, \Delta),$$

where $j = M(\text{males}), F(\text{females})$.

Permanent or anticipated labor market conditions refer to important conditions that local firms and workers know and include in rational decision making. These variables include the anticipated or long-run unemployment rate, anticipated rate of job growth, and anticipated change in the occupational composition of employment. When anticipated unemployment harms workers (households) more than firms (employers), firms or localities with higher anticipated unemployment rates will have higher

equilibrium wage rates than other firms or localities (Hall, Abowd and Ashenfelter, Adams, Topel). That is, higher wage rates compensate for higher probabilities of unemployment. When households (workers) bear most of the cost of geographical and occupational mobility, geographic differences in the anticipated rate of employment growth and in change of occupational composition of employment are also the source of compensating geographical wage differentials (Lilien, Adams, Topel). Thus, positive wage differences provide economic returns to households for geographical or occupational mobility.

Locational differences in the cost of living can be decomposed into effects of prices of goods traded among locations and of nontraded goods and services (Tolley, Kenny and Denslow). With competitive markets, the prices of traded goods in two areas differ by transport costs so that they likely are an insignificant source of cost of living differences. However, prices of nontraded goods and services differ more between two localities. The price of housing-plus-access is a good example for the nontraded good. Furthermore, because housing costs are about 14% to 15% of workers' household expenditures, locational differences in these prices are a significant source of interlocality wage differences.

Areas differ in the quantity and quality of locational amenities. Normal climatic conditions, e.g., average January and July temperature, are characteristics of the local environment that likely matter to households (workers) and possibly to firms. Other studies (e.g., Israeli, Hock and Drake, Kenny and Denslow) have found significant effects of climatic conditions on wage rates.

Labor Supply and Labor Force Participation

Households make labor supply and labor force participation decisions of their members. In this analysis, the focus is on single-family, husband-wife households, where the decisions are for one period, and households are risk neutral about uncertain outcomes including employment or unemployment. This means the expected wage is used in resource allocation decisions.

Participation decisions of farm and rural nonfarm households are analyzed. The nonfarm households are assumed to have only wage and asset income; farm households have asset income, self-employment income from their farm business, and perhaps off-farm wage income. Thus, the wage-labor participation decisions of

farm households are more complex than for rural nonfarm households (Huffman and Lange, Strauss).

The economic decision-making framework of these households is summarized in equations (2)–(5).

$$(2) \quad U = U(T_h^M, T_h^F, Y; \zeta^M, \zeta^F, \Delta, \tau)$$

$$(3n) \quad \bar{T} = T_m^j + T_h^j, T_m^j \geq 0, j = M, F$$

$$(3a) \quad \bar{T} = T_f^j + T_m^j + T_h^j, T_m^j \geq 0, j = M, F$$

$$(4n) \quad (1 - u^M) W_0^M T_m^M + (1 - u^F) W_0^F T_m^F + V = P_y Y$$

$$(4a) \quad (1 - u^M) W_0^M T_m^M + (1 - u^F) W_0^F T_m^F + V + P_Q Q - W_x X + V = P_y Y$$

$$(5a) \quad Q = Q(T_f^M, T_f^F, X; \zeta^M, \zeta^F, \Delta).$$

Notation “*n*” and “*a*” after the equation number refer to nonfarm and farm households, respectively; other equations refer to both types of households.

Farm and nonfarm households derive utility from the leisure time of the husband and wife (T_h^j) and from goods purchased in the market (Y). Household utility also depends on husband's and wife's human capital (ζ^j), local climate (Δ), and other household characteristics (τ), e.g., number of children in the household and commuting distance to service centers.

specific unemployment rates are exogenously determined for the households. Furthermore, firms and households do not know the unanticipated parts of employment growth or unemployment rates. W_o^j is the anticipated wage, given unemployment, when unanticipated local labor disturbances are zero, i.e., $\omega = 0$ in equation (1). Expected household wage income is $(1 - u^M) W_o^M T_m^M + (1 - u^F) W_o^F T_m^F$. Household asset income is V . Farm households also have uncertain self-employment or net income from a farm business ($P_Q Q - W_x X$). Farm output (Q) is produced by inputs of husband's and wife's farm hours (T_f^j) and by purchased inputs (X). The efficiency of the production process is affected by human capital of the husband and wife (ζ^j) and climate (ϕ).³

Households are assumed to face a perfectly elastic supply of the consumption good (Y) at a price P_y . Farm households also face a perfectly elastic supply of inputs at price W_x and perfectly elastic demand for farm output. However, the price of farm output is uncertain when production plans are made, and P_Q denotes the expected price.

For rural nonfarm households, wage labor supply functions are obtained by maximizing (2) subject to (3n) and (4n). For farm households, wage labor supply functions are obtained by maximizing (2) subject to (3a), (4a), and (5a). These wage labor supply equations are:

$$(6n) \quad T_m^j = S_m^j[(1 - u_o^j)W_o^j, (1 - u^k)W_o^k, P_y, V, \zeta^M, \zeta^F, \Delta, \tau], T_m^k > 0, \\ S_m^j[(1 - u^j)W_o^j, P_y, V, \zeta^M, \zeta^F, \Delta, \tau], T_m^k = 0, \quad j, k = M, F; j \neq k.$$

$$(6a) \quad T_m^j = S_m^j[(1 - u^j)W_o^j, (1 - u^k)W_o^k, P_y, V, P_Q, W_x \zeta^M, \zeta^F, \Delta, \tau, \phi], T_m^k > 0; \\ S_m^j[(1 - u^k)W_o^j, P_x, V, P_Q, W_x, \zeta^M, \zeta^F, \Delta, \tau, \phi], T_m^k = 0, \quad j, k = M, F; j \neq k.$$

Farm and nonfarm households receive human time endowments each year (\bar{T}) for the husband and wife, which are considered heterogenous. In nonfarm households, the time of each adult is allocated between work for a wage (T_m^j) and leisure (T_h^j). In farm households, time is allocated among work on their own farm (T_f^j), work for a wage (off farm) (T_m^j), and leisure (T_h^j). In farm and nonfarm households, optimal hours of wage work might be zero in any year. Hence, a nonnegativity constraint is imposed on wage work ($T_m^j \geq 0$).

The cash income of farm and rural nonfarm households is uncertain because of uncertain employment prospects. Thus, the wage rate, given employment, is adjusted for the expected probability of unemployment (u^j). These sex-

Equations (6n) and (6a) show that wage labor supply functions for a given individual have different structures (Huffman and Lange). When both married nonfarm individuals work for a wage, their wage labor supply is a function of their expected anticipated wage rates, price of consumption goods, asset income, their human capital stocks, the local climate, and tastes. For farm households, the expected price of farm output, the price of purchased farm inputs and a technology parameter also determine off-farm wage labor supply.

Wage-labor participation decisions of an in-

³ The effect of a tax on income is excluded from the economic (and econometric) model. This simplification is unlikely to be of major consequence for the empirical results (Mroz).

dividual are modeled as a comparison of his (her) reservation wage and anticipated market wage. The reservation wage equation is derived from the wage-labor supply equation by setting wage work hours equal to zero:

$$(7n) \quad W_r^j = \left(\frac{1}{1 - u^j} \right) G_r^j [P_y, V, \zeta^M, \zeta^F, \Delta, \tau, (1 - u^k), \Omega, \omega = 0, \psi], \\ j, k = M, F; j \neq k.$$

$$(7a) \quad W_r^j = \left(\frac{1}{1 - u^j} \right) G_r^j [P_y, V, P_Q, W_X, \zeta^M, \zeta^F, \Delta, \tau, \phi, \\ (1 - u^k), \Omega, \omega = 0, \psi], \\ j, k = M, F; j \neq k.$$

A nonfarm household member participates in wage work when his (her) reservation wage is less than the anticipated wage in the market.⁴ A farm household member participates in nonfarm wage work when the marginal value of his (her) leisure and (or) farm work hours are less than the anticipated nonfarm wage.

The probability of wage work can be expressed as the probability that an individual's reservation wage is less than his (her) anticipated market wage. For the i th household and j th married individual, define

$$D_i^j = \begin{cases} 1 & \text{if } j\text{th individual works for a wage} \\ 0 & \text{otherwise} \end{cases}, \\ j = M, F;$$

then the probability of wage work for the i th individual is

$$(8) \quad P_r\{D_i^j = 1\} = F\{W_{ri}^j < W_{oi}^j\}; j = M, F, \text{ or}$$

$$(8a) \quad P_r\{D_i^j = 1\} = F[P_y, V, \zeta^M, \zeta^F, \Delta, \tau, \Omega, \\ (1 - u^j), (1 - u^k)], \\ j, k = M, F; j \neq k, \text{ and}$$

$$(8n) \quad P_r\{D = 1\} = F[P_y, V, P_Q, W_X, \phi, \zeta^M, \zeta^F, \Delta, \tau, \Omega, \\ (1 - u^j), (1 - u^k)], \\ j, k = M, F; j \neq k,$$

where $F(\cdot)$ is a distribution function. Variables that explain the probability of wage work enter an individual's labor demand and labor supply functions, except for the individual's anticipated

wage rate. When the labor supply schedule has a positive slope, variables that cause the labor supply curve to shift to the left will increase the reservation wage and reduce the probability of wage work. A change in a variable that raises the market wage—raises the labor demand curve—will increase the probability of wage work.

Selected variables are examined for their effects on the probability of wage work. An increase of an individual's schooling will increase the anticipated market wage and reservation wage. The net effect on the probability of wage work is a priori ambiguous, but other studies (e.g., Heckman and MaCurdy 1980, 1982; Huffman and Lange) have found a strong positive effect of an individual's schooling on the probability of wage work for married farm and nonfarm males and females in the United States.

When leisure is a normal good, a higher expected price of farm output reduces the probability of wage work by couples who operate a farm business. The reason is that the quantity demanded of husband's and wife's farm labor increases, provided their farm hours are a normal input and the quantity of their leisure demanded increases due to the increase of expected profit. Higher farm input prices change the probability of wage work in an a priori ambiguous direction. Hired (nonfamily) labor and family labor are heterogenous. If hired farm labor and husband's and wife's farm labor are gross substitutes, then a higher wage for hired labor will cause a rightward shift of the demand for husband's and wife's farm labor. A higher input price reduces expected farm profit and reduces the demand for leisure of the husband and wife. Thus, the net effect on the reservation wage and probability of wage work is a priori ambiguous. A change in the price of other inputs yields a similar conclusion.

The effects of local labor market conditions depend partially upon expectations. If the demand for leisure increases as the expected wage decreases, a higher expected local unemployment rate will raise an individuals' reservation wage. When anticipated unemployment hurts workers more than firms, firms or localities that have higher expected unemployment rates will pay higher wage rates. Thus, the net effect of anticipated unemployment on the probability of wage work depends on which of these changes is largest. Localities having more rapid anticipated job growth are expected to pay higher wage rates than other areas and hence will increase the probability of wage work. On the other hand,

⁴ Alternatively, decisions can be made by comparing indirect utility functions associated with different outcomes.

unanticipated changes in local labor market conditions are not expected to affect the probability of wage work. These disturbances can at best be poorly forecasted and at worst cannot be forecasted. The anticipated wage rates are higher in these localities, while the reservation wage likely is unaffected.

The Data and Econometric Model

The econometric model incorporates effects of local economic conditions on wage labor demand and probability of wage work of married rural males and females. Focusing on males and females provides a better picture of the total effect on households and on differences resulting from gender. Farm and rural nonfarm households from the Current Population Surveys (CPS) and having economic activity in 1978, 1979, 1981, and 1982 are the decision units to be studied.

The Data

The CPS is a monthly survey containing information about the employment status of members of approximately 60,000 interviewed households residing in every state of the United States. The annual demographic file (March) contains information on labor force participation, employment, and earnings of household members during the calendar year before the survey. Starting in 1977, the state of residence and farm-nonfarm residence of each household are identified.

One sample consists of nonmetropolitan-nonfarm households where the husband and wife are present and no self-employment income was received. This is the closest definition to rural nonfarm because households having rural nonfarm residence are not identified in the CPS. This sample comprises "rural nonfarm" wage earning households. The other sample consists of husband-wife households that have a farm residence and self-employed income from farming. In both samples, households having a residence in the contiguous forty-eight states, except for New England, are included. Households in New England were excluded because of the lack of importance of agriculture in those states. These two samples from the forty-two states consist of about 8,115 rural nonfarm households and 1,466 farm households per year.

Local markets are defined as state units in this

study. A state is the smallest geographic unit in which a CPS household can be identified. States are also the smallest political-economic-geographic unit for which annual data are collected on employment, unemployment, and agricultural prices. In addition, government programs frequently target state units. Other recent studies (e.g., Adams, Topel) have used state units as labor markets.

The years 1978–82 give variations in local economic conditions that affect wage and participation rates. This period was chosen for several reasons. The CPS first identified the farm-nonfarm residence of households in 1977. Second, the period 1975–79 is the trough-to-peak part of a national business-cycle expansion (Executive Office of the President). The national average unemployment declined from 8.3% in 1975, to 5.8% in 1979. Net farm income was relatively good in the late 1970s. The period starting in 1980 contained a business-cycle contraction. The national unemployment rate rose from 7% in 1980 to 9.5% in 1982–83. The sharp rise of real interest rates and fall in the value of the U.S. dollar contributed to the drop in net farm income during 1981 and 1982. Although the depression of the farm economy continued after 1982, extending the analysis through 1983 did not seem wise because the first large government payment-in-kind (PIK) programs occurred in 1983. Third, the data in table 2 show relatively large geographical variation in shocks to labor demand during this period. Fourth, Lilien has shown that employment growth was unequally distributed across U.S. industries in the 1970s. Significant shifts of the occupational-industrial mix of employment occurred, especially a rise in the share of employment in services, finance, insurance and real estate but a decrease in manufacturing.

When the four cross-sectional files are combined, the data on forty-two states and four years gives 168 potentially distinct observations on different local economic conditions. Although data for four years are used, it is not a panel consisting of the same households. About 25% of the CPS households in any year are replaced.

Empirical Definitions

Definitions and sample mean values of the variables are presented in table 3. More details are presented below on the derivation of selected variables.

Average hourly wage rates are derived for ru-

Table 3. Variable Names and Sample Means, Rural Married Couples 1978–79, 1981–82

Symbol	Variable Description	Sample Mean	
		Nonfarm	Farm
<i>Individual/household</i>			
AGEM	Husband's age (yrs)	47.0	50.5
AGEF	Wife's age (yrs)	43.9	47.2
EDM	Husband's schooling (yrs)	11.5	11.3
EDF	Wife's schooling (yrs)	11.6	11.8
RACE	1 if nonwhite; 0 otherwise	.07	.03
KIDS06	Number of children under age 6	.31	.27
KIDS618	Number of children ages 6–18	.66	.69
ASSETINC	Household real nonwage and nonfarm income (1967 prices) ^a	\$10,386 ^a	\$10,701 ^a
<i>Local labor market conditions</i>			
PJOBGR	Predicted state employment growth rate (see text)	2.17	2.06
PURATE	Predicted state unemployment rate (see text)	7.46	7.18
ΔSHRSER	Change of share of a state's jobs in serv. occupation (previous 2 yrs.)	1.02	.91
ESHOCK	Relative state employment growth shock (see text)	.08	.15
RURATE	Residual state unemployment rate (see text)	−.37	−.38
<i>Cost of living and locational amenities</i>			
PLAND	State average price of agricultural land in 1978 (\$1,000/acres)	.91 ^a	.79 ^a
URBAN	Percentage of state population urban	.68	.66
JAN	Normal January ave. temperature (degree F)	34.1	29.7
JULY	Normal July ave. temperature (degree F)	75.9	75.1
<i>Agricultural prices and climate</i>			
PCROP	State real price index for crops (1967 prices)		.444 ^a
PLIVE	State real price index for livestock (1967 prices)		.517 ^a
FARMWAGE	State real wage rate for hired farm labor (1967 prices)		.504 ^a
POTINP	State real price index for nonlabor farm input (1967 prices)		.536 ^a
RAIN	State annual average precipitation (inches)		35.7
GDD	State average growing season length—growing degree days (1,0005)		3.336
<i>Regional dummies and trend</i>			
NC	1 for resident in North Central Region; 0 otherwise	.28	.46
SOUTH	1 for resident in South; 0 otherwise	.51	.38
WEST	1 for resident in West; 0 otherwise	.06	.12
TIME	Trend	3.00	3.00
<i>Dependent variables</i>			
WAGEM	Real married male nonfarm wage (\$/hr, 1967 prices)	\$2.87 ^a	
WAGEF	Real married female nonfarm wage (\$/hr, 1967 prices)	\$1.66 ^a	
D ^M	1 if husband works for wage; 0 otherwise	.75	.43
D ^F	1 if wife works for a wage; 0 otherwise	.54	.39

^a Geometric mean. All other numbers are arithmetic means.

ral nonfarm married males and females. For individuals in the rural nonfarm wage work households, the average wage of an individual is his (her) wages and salaries for the year preceding the survey divided by the product of his (her) hours worked per week last year and weeks worked last year. An accurate measure of the average wage rate cannot be computed for individuals in a household with self-employment income because hours worked include hours at all jobs, both wage work and self-employment. Thus, average wage rates are not available for CPS farm household members. Nominal wage rates are deflated by the consumer price index.

Five measures of local labor market conditions are derived. The predicted state employment growth rate ($PJOBGR_t$) is the difference in forecasted values of the natural logarithm of a state's private sector employment in t and $t - 1$. The forecasts were obtained from a regression of the natural logarithm of employment, 1968–82, on a quadratic trend. A state's unemployment rate was measured for all private sector employees rather than having separate rates for males and females. The predicted state unemployment rate ($PURATE_t$) measures the anticipated local unemployment rate. It is obtained from a regression of a state's annual unemployment rate, 1968–82, on quadratic trend. The change in the share of a state's employment that is in the service sector ($\Delta SHRSER_t$) indicates changes in the occupational mix of local labor demand. It is defined as the share in t minus the share in $t - 2$. Service jobs include employment in services, transportation, government, finance, and wholesale and retail trade. The derivation of the relative shocks to labor demand in state labor markets ($ESHOCK_t$) is described above. In this study, these shocks are unanticipated by firms and workers. The residual or unanticipated unemployment rates ($RURATE_t$) is the actual unemployment rate in t minus the predicted unemployment rate for t .

Geographical differences in the cost of living and locational amenities are tied to cost of housing-plus-access and climate. The price of land is a major part of the cost of housing-plus-access. For households living in rural areas, the base price of land is represented by the average agricultural land price in 1978 (U.S. Dep. of Commerce 1980). In addition, the price of housing-plus-access increases as the percentage of the population living in urban areas increases because the cost of land plus commuting is larger in urban areas. When land prices and wage rates are positively associated and housing and hus-

band's and wife's leisure are substitutes, an increase of P_{LAND} will increase the reservation wage. This makes the effect of P_{LAND} on the probability of wage work a priori uncertain. However, if housing and husband's and wife's leisure are complements, their reservation wage rates will decline. The percentage of the population living in urban areas in 1980 (U.S. Dep. of Commerce 1981) is used as a second proxy for the cost of housing-plus-access. For locational amenities, thirty-year (1950–80) normal average January and average July temperatures (Weiss, Whittington, and Teigen) were used. Kenny and Censlow and Hoch and Drake found nonlinear effects of these temperatures on log wage rates in earlier studies.

The profitability of local agriculture is represented by indexes of agricultural prices and agricultural climate. Indexes of crop prices, livestock prices, wage for farm labor, and prices of other inputs are derived and deflated by the consumer price index. Output price indexes for crops and livestock are constructed because the average labor intensity is significantly different for these output groups (Huffman and Evenson, chap. 10). The crop price index is composed of prices of twenty-six different commodities or commodity groups. The livestock price index is composed of seven commodity groups. The expected prices used to derive the Fisher-type output price indexes are primarily one-year lagged prices of the commodities (Huffman and Evenson, chap. 10).

Input prices are split into two groups, farm labor and other inputs. The price of farm labor is the hourly wage paid to employees working for cash wages only. The nonlabor input prices include fertilizer, feed, capital, seed, land, and miscellaneous inputs. Current prices are used to derive Fisher-type price indexes of these inputs (Huffman and Evenson, chap. 10). Both output and input price indexes are deflated by the consumer price index.

Normal annual precipitation and normal growing-degree-days are important climatic variables for agricultural production. Normal annual rainfall is a twenty-five-year average of annual precipitation (Weiss, Whittington, and Teigen). Natural precipitation is the primary source of water for much of U.S. agriculture. However, in low precipitation areas, irrigation is a costly substitute. Accumulated growing degree days, GDD , is a measure of accumulated heat units from a temperature range that is particularly favorable to corn production (U.S. Dep. Agriculture and U.S. Dep. Commerce; U.S. Dep.

Commerce 1971, 1981). Corn is grown in almost every state, but more generally the index is highly correlated with good growing conditions for warm-season crops.

Household asset income reflects earnings from interest, dividends, and rental property deflated by the consumer price index. Thus, all income- and work-conditioned transfers are excluded.

The Econometric Model

The econometric model consists of two labor demand equations and two wage-participation equations. The empirical specification of the labor demand equations is similar for married males and females:

$$(9) \quad \ln WAGE_i^j = \alpha_1^j + \alpha_2^j EXP_i + \alpha_3^j EXP_i^2 + \alpha_4^j ED_i + \alpha_5^j RACE_i + \alpha_6^j PJOBGR_i \\ + \alpha_7^j PURATE_i + \alpha_8^j \Delta SHRSER_i + \alpha_9^j ESHOCK_i + \alpha_{10}^j RURATE_i \\ + \alpha_{11}^j \ln PLAND_i + \alpha_{12}^j URBAN_i + \alpha_{13}^j JAN_i + \alpha_{14}^j JAN_i^2 + \alpha_{15}^j JULY_i \\ + \alpha_{16}^j JULY_i^2 + \alpha_{17}^j NC_i + \alpha_{18}^j SOUTH_i + \alpha_{19}^j WEST_i + \alpha_{20}^j TIME_i + \alpha_{21}^j \lambda_i^j \\ + \epsilon_i^j, i = 1, \dots, n, j = M, F.$$

The natural logarithm of an individual's real wage is expressed as a function of his (her) own human characteristics—experience, experience squared, education, race—and job/local conditions that are potential sources of geographical wage differentials. The last group of variables includes sets of variables for local labor market conditions, cost of living and locational amenities, and regional dummy variables. A time trend and sample selectivity variables (λ_i^j) are also included in each equation.

Equation (9) is quadratic in experience and in January and July temperatures but not in other variables. This choice was largely based on evidence reported in other studies (e.g., Adams, Topel, Kenny and Denslow) and preliminary fits of the wage equations. Experience is defined as an individual's age minus years of schooling completed minus 6. This measure of experience is a reasonable proxy for useful work experience of males but less so for females engaged in household activities. It is less endogenous to current labor market decisions than actual experience (Heckman and MaCurdy). When a sample selection variable is included in the wage equation, sample selection bias is unlikely to be associated with the use of a work experience variable (Mroz).

The regional dummy variables may contain redundant information about labor demand. If the set of variables representing local labor market conditions and cost of living and locational

amenities proxy relatively well the sources of geographical wage differentials, then the regional dummy variables will not make a statistically significant contribution to real wage rates. When women spend more time out of the labor force and are more geographically immobile than men, women's wage rates likely will be less responsive to their measured human capital and to local economic conditions (Mincer). The coefficients of variables in the female wage equation then will be smaller than in the male equation.

Sample selectivity and autocorrelation are potential problems in the wage equation. If a sample selection variable was not included in equation (9), the disturbance term of the wage equation would have a nonzero mean because the equation is fitted to a nonrandom subset of

the total population (Heckman). This is a potential source of statistical bias in estimated coefficients. With a selection variable included, the disturbance has a zero mean and a normal distribution.

The data files consist of two adjacent-year cross sections (1978–79, 1981–82) that are separated by one year. Some autocorrelation might be expected in adjacent year observations on the same individual, but observations that are one or more years apart are less likely to be correlated. This short, disjointed time series, where the composition of the sample changes over time, is not conducive to correction for autocorrelation. Failure to correct for autocorrelation when it is present results in some loss of estimation efficiency, but the least-squares estimator is unbiased or consistent (Johnston). Contemporaneous correlation of disturbances in the two wage equations might occur. However, because the observations in the wage equations of the married males and females are not equal, the two wage equations of the married males and females are not equal, the two wage equations cannot be estimated jointly in the seemingly unrelated regression model. Ignoring contemporaneous cross-equation correlation of disturbances results in some loss of estimation efficiency (Johnston).

The empirical specification of the probability of the j th married individual in the i th farm household participating in wage work is

(10a)

$$\begin{aligned} \Pr(D_i^j = 1) = F[& \beta_1^j + \beta_2^j AGEM_i + \beta_3^j AGEM_i^2 + \beta_4^j EDM_i + \beta_5^j EDF_i + \beta_6^j RACE_i \\ & + \beta_7^j KIDS06_i + \beta_8^j KIDS618_i + \beta_9^j \ln ASSETING_i + \beta_{10}^j PJOBGR_i + \beta_{11}^j PURATE_i \\ & + \beta_{12}^j \Delta SHRSE_i + \beta_{13}^j ESHOCK_i + \beta_{14}^j RURATE_i + \beta_{15}^j \ln PLAND_i + \beta_{16}^j URBAN_i \\ & + \beta_{17}^j JAN_i + \beta_{18}^j JAN_i^2 + \beta_{19}^j JULY_i + \beta_{20}^j JULY_i^2 + \beta_{21}^j \ln PCROP_i \\ & + \beta_{22}^j \ln PLIVE_i + \beta_{23}^j \ln FARMWAGE_i + \beta_{24}^j \ln POTINP_i + \beta_{25}^j GDD_i + \beta_{26}^j RAIN_i \\ & + \beta_{27}^j RAIN_i \bullet GDD_i + \beta_{28}^j NC_i + \beta_{29}^j SOUTH_i + \beta_{30}^j WEST_i + \beta_{31}^j TIME_{ij}] j = M, F, \end{aligned}$$

where $F(\cdot)$ is the normal distribution function. The participation equations for rural nonfarm household members are similar, except that prices of agricultural outputs and inputs, annual precipitation, and the length of growing season are excluded. This probability is a function of a set of variables representing an individual's own characteristics, spouse characteristics, household characteristics, and local conditions.⁵ A time trend is also included.

Equation (10) is a reduced-form specification, including only variables in the labor supply or labor demand functions (Huffman and Lange). The husband's age (and age squared) controls for nonlinear life-cycle and work-experience effects when education is held constant. Age and experience are highly correlated, so experience is not included as a separate variable. Because husband's and wife's ages are also highly correlated, only the husband's age is used for explaining both the husband's and wife's probability of wage work.

Given that participation decisions of a husband and wife in farm and nonfarm households are assumed to be joint within a household-optimizing framework, the probability of a married individual participating in wage work is affected by some of their spouse's characteristics. Also, these decisions are affected by random or unmeasured shocks to labor supply (reservation wage) and labor demand. These shocks likely are across spouses (Huffman and Lange). Thus, the estimation procedure for equation (10) is bivariate probit. If a husband and wife are affected similarly by a given shock, the correlation between these disturbances will be positive, and vice versa.

The Results

Results from testing hypotheses about the effects of local economic conditions and other

variables on labor demand for rural nonfarm married males and females and on the probability of wage labor participation of married males and females in farm and rural nonfarm households are reported in this section.

Labor Demand

Labor demand equations are fitted to the data for 24,571 married rural nonfarm males and 17,508 married rural nonfarm females. These equations (9) are fitted by least squares with an instrumental variable included to control for sample selectivity. Conclusions reached about labor demand for married rural nonfarm males and females likely are applicable to married farm males and females.

Estimates of four labor demand functions are reported in table 4; two for males and two for females. The second equation excludes the regional dummy variables. A test of the null hypothesis that the coefficients of the three regional dummy variables are jointly equal to zero is rejected for males but not for females. The sample value of the F -statistic is 5.08 for males and 1.90 for females, and the critical value of the F -statistic with 3 and infinite degrees of freedom is 3.79 at the 1% significance level. Thus, for males the eleven variables representing local labor market conditions, cost of living differences, and location amenities do not capture all of the geographical differences in wage rates. Furthermore, the long history of wages being lower in the South is no longer supported. Male wages are higher in the South than in other regions, and female wages are not lower.

In the wage equations, all of the coefficients of the human characteristics have expected signs and are significantly different from zero at the 1% level. An increase of an individual's experience has first a positive but diminishing marginal effect on the real wage. The maximum effect occurs at 36.9 years for males and 31.5 years for females. This pattern has been reported in many studies. However, the \log_e wage-experience relationship is more convex for males than

⁵ Although the number of children at home and the amount of household asset income is endogenous in a lifetime planning horizon, Mroz found that these variables were not endogenous in his tests. They are exogenous in our study.

Note: The *t*-ratios are conditioned on the sample selection variables.

for females. This result is consistent with married females having on average less actual labor market experience for any given measured experience than for married males (Mincer and Ofek). Males may also make larger investments in experience during their early work-life than females.

A one-year increase in schooling causes a larger percentage increase of the female than the male wage, 7.1% versus 5.5%. These relative magnitudes are consistent with some results reported in other studies, e.g., Topel for males and Gerner and Zick for females. Although the average wage for married rural nonfarm working females in the CPS sample is 57.8% of the wage for males, the marginal increase of the real wage is larger for males than for females (\$.16 versus \$.12 per hour).

Nonwhite rural nonfarm males earn 20% less than rural nonfarm white males, other measured variables equal, and nonwhite females earn 6.5% less than white females. Topel found an 18% difference in wages of white and nonwhite males for 1976–79. Other studies have also shown large gaps in the wages of white and black males on average but little or no gap in white and black women's wage ratios (e.g., Hammermesh and Rees).

All of the signs of coefficients on variables representing local labor market conditions are positive, except for the unanticipated unemployment rate, in both the male and female wage equations. They are all consistent with hypotheses developed earlier. Most coefficients in the male wage equation are significantly different from zero at the 5% level. For females, the effects of the local labor market variables are smaller for anticipated variables than for males but are as large or larger for unanticipated variables. Except for the unanticipated unemployment rate, the local labor market variables are statistically weaker in the female than in the male wage equations.

The real wage rates of married males incorporate compensation for local market conditions that can be anticipated by employers and workers. The evidence, however, is weaker for females. This outcome is expected when married females spend a smaller share of their time in the labor force and are tied to their husband's locational choice (Mincer). For married males, wage rates are higher in localities with higher expected rates of employment growth and higher expected unemployment rates.

The wage premium in localities having higher expected growth of labor demand compensates

males for the costs of geographical (and possibly occupational) mobility. Topel found a similar effect. Our results show that a 1% increase of the expected growth rate of local employment increases the male real wage by 1.5% to 2.5%. For females, the marginal effect is about 1%. These results imply that married rural males and females in the upper Midwest experienced significant reductions in real wage rates during the early 1980s when employment growth rates fell far below (about 2 percentage points) the national average (see table 1).

Localities with higher anticipated unemployment rates also pay higher rural wage rates for males. This result is similar to the findings of Abov and Ashenfelter, of Adams, and of Topel. Localities (firms) with higher expected unemployment rates pay a premium to compensate male workers for bearing this risk; the evidence is much weaker for females. Again, this finding is consistent with greater immobility of married females than males. These results imply the wage premium associated with higher anticipated unemployment rates is large enough for males to keep expected real wage rates approximately unaffected.

An increase locally of the share of service jobs increases the real wage. The effect is significantly different from zero at the 5% level for males but not for females. Although service jobs span a wide range of skills from motel and restaurant staff to investment bankers, compensation is needed to create the incentives for males to invest in skills and change occupations.

Real wage rates respond to unanticipated changes in local labor market conditions in a way that is consistent with employers and employees sharing good and bad outcomes. Topel found similar effects for wage rates of nonfarm males. The coefficients of *ESHOCK* are significantly different from zero at the 7% level [table 4, equation (1)] in the male wage equation and at the 20% level in the females' wage equation. The coefficient of *RURATE* is significantly different from zero at the 10% level in the female wage equation but only at the 25% level in the male wage equation. Other studies have not considered the effect of unanticipated unemployment on the female wage. Heckman and MaCurdy found a negative effect of the current local unemployment rate on the female wage. However, Adams found a significant positive effect of unanticipated unemployment rate on the male wage. Thus, our results differ slightly from other studies for the effects of unanticipated unemployment on the female

real wage.⁶ This result is reasonable if married males on average have significantly larger investment in firm-specific human capital than married females. Workers having firm-specific human capital are less likely to be laid off (Becker).

Wage rates of males and females differ because of local differences in cost of living and locational amenities. Under the null hypothesis that the six coefficients of these variables are jointly equal to zero, the sample value of the *F*-statistic is 19.8 for males and 8.9 for females. The critical value of the *F*-statistic with 6 and infinite degrees of freedom at the 1% significance level is 2.1. Thus, the null hypothesis of no effect is rejected.

Cost of living differences matter. A larger land price increases significantly the wage rates of males and females. The elasticities are .060–.073 for males and .053–.056 for females. These magnitudes fall in the range predicted by Kenny and Denslow for wage adjustments to compensate for home-site cost differences when housing costs are 15% of consumption expenditures and the price of the home site accounts for 21% of the value of a home, including site. An increase of the urban share of the population increases significantly the wage rate of males. However, *URBAN* does not statistically significantly affect female wages.

Climate is a proxy for locational amenities, and the effects of *JAN* and *JULY* on wage rates are conditioned by whether the regional dummy variables are included. Because *JAN* and *JULY* are correlated with the regional dummy variables, the best measure of winter and summer temperatures on wage rates is obtained when the regional dummy variables are excluded. The effect of *JAN* on \log_e male wage is quadratic and statistically significant. In the female wage equation, *JAN* and *JAN*² do not have statistically significant effects. The effects of *JULY* on \log_e wage are quadratic and statistically significant for males and females. For males, an increase of *JULY* first causes a reduction of the wage but at a decreasing rate until it reaches the low point at 82°F which is the maximum observed value. This type of relationship was also found by Hoch and Drake. For females, the quadratic effect goes in the opposite direction. The peak occurs at 72°F

which is near the bottom of the observed values and corresponds to average July temperatures in Pennsylvania and South Dakota. Thus, for most of the observed values of *JULY*, an increase of *JULY* reduces the wage rates of males and females.

Participation in Wage Work

The bivariate probit estimates of the equations explaining the probability of wage work for farm and rural nonfarm couples are reported in table 5. The equations were fitted to 32,662 observations on rural nonfarm households and 5,865 observations on farm households. Marginal effects of the regressors on the probability of wage work are evaluated at the sample mean and reported in table 6.

The first two columns of table 5 present results for rural nonfarm couples; the last two columns are for farm couples. The estimated cross-equation correlation coefficient of the disturbances in the participation equations is positive—0.26 for farm couples and 0.19 for rural nonfarm couples—and significantly different from zero at the 1% level. These results imply: (a) that the random disturbances in married male and female wage-work participation decisions are affected in the same direction by random shocks (or unmeasured effects), and (b) that the wage-work participation decisions of married males and females are not statistically independent.

For farm and nonfarm males and rural nonfarm females, the life-cycle effect on probability of wage work is quadratic. At young ages, a higher age increases the probability of wage work. The maximum effect occurs at age 26.2 and 33.2 for farm and rural nonfarm males, respectively, and at age 20.8 for nonfarm females. At older ages, the probability of wage work decreases as age increases. For farm females, the probability of wage work is largest at a young age and may be dominated by cohort effects. Labor force participation rates of married women in younger cohorts are significantly higher than in older cohorts (Killingsworth and Heckman).

A husband or wife who has more schooling has a higher probability of wage work. Additional schooling raises an individual's market wage by more than it raises his/her reservation wage. For nonfarm females these results for females are similar to those of Heckman and of Nakamura and Nakamura. For farm males, the

⁶ The null hypothesis that the 5 coefficients of the local labor market variables in the labor demand equation for females are jointly equal to zero cannot be rejected at the 1% significance level. For equation (3), table 4, the sample value of the *F*-statistic is 1.14, and the critical value for 5 and infinite degrees of freedom is 3.02 at the 1% significance level.

results are similar to those of Sumner and of Huffman and Lange. The marginal effect of a year of female schooling on the probability of wage work is larger than that of male schooling (.41 versus .91 for nonfarm males and females and .15 versus .16 for farm males and females). Thus, a year of schooling seems to increase the difference between a wife's reservation and market wage relatively more than for her husband. This is consistent with results reported by Huffman and Lange for a different data set. Also, the marginal effect of schooling on the probability of wage work for a given gender is larger for rural nonfarm than for farm adults.

Although cross-person effects of education are seldom included (e.g., Heckman; Nakamura and Nakamura; Heckman and MaCurdy 1980, 1982; Sumner), negative and statistically significant effects of a farm or rural nonfarm husband's schooling on his wife's participation and of farm wife's schooling on her husband's wage work participation occur. Huffman and Lange also found a similar negative effect of a farm wife's schooling on her husband's probability of wage work. For the rural nonfarm male, additional schooling of the wife tends to increase the probability of working for a wage.

Additional children at home under age 18 have well-known and statistically significant negative effects on the probability of wage work by married females. The largest reduction occurs for additional children under age six—about 5% per child. For older children, the negative marginal effect is larger for farm than for rural nonfarm married females. The coefficients of *KIDS06* and *KIDS618* are negative in both participation equations for married males, but they are generally weaker statistically. These results imply that additional children at home raise the reservation wage of married women relatively more than the reservation wage of married men.

Although no other study has examined the effects of local labor market conditions on the probability of wage work, the effects of these variables are largely as expected. Anticipated variables have statistically stronger effects than unanticipated ones. Higher local employment growth raises the market wage of males and females, and it increases the probability of wage work. These effects are significantly different from zero at the 5% level, except for farm wives. Recall that the labor demand equations showed that a 1% rise of the expected unemployment rate caused the male wage rate to rise by 1.1% to 1.2% but the female wage rate to rise by only 0.3% to 0.4%. Thus, if households are risk neu-

tral, the positive effects of *PURATE* on the participation of farm and nonfarm males are consistent. There is no significant effect, however, on the probability of participation of farm females. A larger Δ *SHRSER* does not significantly affect the probability of wage work of males or females, although it does increase the wage rate of males. The relative employment shocks and unanticipated unemployment rate do not have statistically significant effects either.

The positive and statistically different from zero effect of *PLAND* on the probabilities of wage work implies that market wage effects are larger than reservation wage effects. The effects of January and July temperatures on the probability of wage work are mixtures of effects through the market wage and reservation wage. Statistically significant effects on participation occur for nonfarm females and farm males. For farm males, a higher *JAN* first increases the probability of wage work; the peak effect occurs at 26°F; and then it decreases.

For farm households, the farm output and input price indexes have consistent signs, and their marginal effects are larger and stronger in the husband's participation equation. A drop of crop and livestock output prices increases the probability of wage work of husbands and wives. A higher farm wage increases the probability of off-farm wage work by husbands. Other input prices have negative coefficients, but they are not significantly different from zero. Agricultural climatic effects are important for farm males. Larger *RAIN* or *GDD* has a negative impact on labor force participation when these effects are evaluated at the sample mean.

Except for women living in the South, the regional effects are not significantly different from zero. Married women living in the South, however, have a lower probability of wage work than women in the Northeast. Other things equal, the reduction is about 1% for rural nonfarm women and 5.5% for farm women. The probability of wage work for rural nonfarm women has a positive and statistically significant trend. None of the other coefficients of *TIME* is significant.

Conclusions and Implications

This study has shown that wage premiums exist for localities anticipating labor demand growth, higher unemployment rates, larger shares of employment in services, and higher costs of living. Unanticipated negative disturbances in local labor markets associated with employment growth

and unemployment reduce wage rates. Male wage rates are more responsive to anticipated changes in local labor market conditions, and female wage rates are more responsive to unanticipated changes. The differences by gender for anticipated effects reflect less time spent by females in the labor force. Women's wage rates bear a greater burden of negative unanticipated labor market outcomes because they are more geographically and occupationally immobile.

Labor force participation decisions of households are also affected by changes in anticipated local economic conditions. For farm households, the probability of wage work increases when expected farm output prices decline and decreases when local labor demand grows. Given the general trend toward larger farms, the results show that existing agriculture is significantly easier for farm households that reside in localities where nonfarm employment is expected to grow rapidly. These effects, however, pull more strongly on males than females. However, participation by farm and nonfarm couples is unaffected by unanticipated labor market outcomes.

The main policy recommendations are that (a) public information be made available to firms and households about anticipated changes in all local labor markets, (b) regionally targeted stabilization policies be employed to moderate unanticipated changes in local labor demand, and (c) tax credits or other incentives be given to workers to hasten their movement from slow growing regions and occupations to rapidly growing ones. Future research could extend this analysis through the late 1980s when national economic conditions and local labor fluctuations were moderate, and examine the effects of local economic conditions on hours of wage work through effects on wage rates.

The Impact of Wage Differentials on Choosing to Work in Agriculture

Jeffrey M. Perloff

Based on a model of industry choice and wage determination, a 1% increase in the relative wage in agriculture increases the probability that a nonurban male with no more than a ninth-grade education works in agriculture by 3.37% at the sample mean and by 1.3% when averaged over the entire sample. A 10% increase in wages may increase the proportion of those males who choose to work in agriculture by nearly a quarter.

Key words: agriculture, industry choice, labor supply, sample selection, wages.

The likelihood of nonagricultural workers joining the agricultural work force in response to an increase in the agricultural wage is estimated in this study. Knowing the responsiveness of the labor supply to wage differentials is important for evaluating many public policies. For example, if the Immigration Reform and Control Act of 1986 (IRCA) eventually restricts the supply of ineligible immigrant labor in the United States, many farmers and legislators fear large wage increases, which will lead to significant crop losses (at least in the short run) or mass noncompliance with the law. How realistic are the fears that large wage adjustments will be required to equilibrate the hired farm worker labor market is assessed in this study.

The study is based on 1988 data from the U.S. Department of Labor, Bureau of Labor Statistics Current Population Survey (CPS), which is a random sample covering all sectors of the economy. The decision to work in the agricultural or the nonagricultural sectors and wages in each sector, controlling for choice of sector, are simultaneously determined. Then the empirically estimated model is used to simulate the increase in the share of agricultural workers from a given increase in the relative agricultural wage.

In the first section, the basic modeling meth-

odology is developed. The data set is described and summary statistics for the key variables are presented in the second section. The empirical results are discussed in the third section. Simulations are used in the next section to show the likely response of workers to higher wages in the agricultural sector. In the final section, inferences and conclusions are drawn from the analyses.

Methodology

A model of industry choice and wages by industry is used to examine the effect of relative wages and nonwage factors on industry choice. The model is a variant of those of Lee, Willis and Rosen, Nakosteen and Zimmer, and Robinson and Tomes. In this model, the natural logarithms of the hourly earnings ("wages") in the agricultural (w_a) and nonagricultural (w_n) sectors are a function of demographic and individual characteristics (X_a and X_n) and unmeasured sources of individual differences (ε_a and ε_n), and the impact of individual characteristics on wages may vary across the sectors:

$$(1) \quad w_a = X'_a \beta_a + \varepsilon_a, \text{ and}$$

$$(2) \quad w_n = X'_n \beta_n + \varepsilon_n.$$

An individual's wage in a given sector is observed only if the individual is working in that sector at the time of the CPS interview.

An individual's choice of sector may depend on nonwage factors as well as the relative wage in the two sectors. Agricultural work is more physically taxing and dangerous than many other types of work. However, many people prefer

working outside in agriculture to an indoor job. Let c be the cost or benefit (disutility or utility) of working in agriculture relative to working in another industry. This (unobserved) variable is a function of a worker's characteristics, Z :

$$(3) \quad c = Z'\delta + \varepsilon_c.$$

The worker compares this cost or benefit to the relative wage in agriculture. The wage ratio (R) between agricultural and nonagricultural sectors is approximated by the difference in the natural logarithms of these wages:

$$(4) \quad R \approx w_a - w_n.$$

The difference in the logs is a close approximation of the ratio for small differences. Alternatively, one can define R as the log wage difference so that equation (4) holds exactly.

The worker chooses to work in agriculture (industry choice, i , equals 1) only if the total benefit to working in agriculture, $R - c$, is positive:

$$(5) \quad \begin{aligned} i &= 1 && \text{if } R - c > 0, \text{ and} \\ i &= 0 && \text{if } R - c \leq 0. \end{aligned}$$

If $i = 1$, then the observed wage is w_a ; otherwise, the observed wage is w_n .

The disturbance terms (ε_a , ε_n , and ε_c) in equations (1), (2), and (3) are assumed jointly normally distributed. As a result, a probit estimation technique can be used to estimate the choice of industry equation (5). Substituting for R in equation (5) using equations (4), (1), and (2) and for c using (3), we obtain a reduced-form industry choice equation,

$$(6) \quad \begin{aligned} i &= 1 \text{ if } X'_a\beta_a - X'_n\beta_n - Z'\delta - \varepsilon_c > 0, \text{ and} \\ i &= 0 \text{ if } X'_a\beta_a - X'_n\beta_n - Z'\delta - \varepsilon_c \leq 0, \end{aligned}$$

which can be estimated using probit with the exogenous variables (X_a , X_n , and Z) in equations (1), (2), and (3) on the right-hand side. Conditional on industry choice, as determined by equation (6), the hourly earnings equations (1) and (2) can be estimated using Heckman's technique to compensate for sample selection bias. If equations (1) and (2) were estimated using ordinary least squares techniques, the estimates would be biased because workers are not randomly assigned to the agricultural and nonagricultural sectors. That is, the unobserved individual difference or disturbance terms (ε_a and ε_n) would not be normally distributed if we examine data for only those workers observed in each sector.

Based on the consistently estimated wage equations, (1) and (2), the estimated wage differential is $\hat{R} = X'_a\hat{\beta}_a - X'_n\hat{\beta}_n$. That is, although we observe a worker's wage in one sector only, these equations can be used to determine the relative wage. Substituting this estimated value for R in equation (5), the structural probit for industry choice can then be estimated.

The key exogenous variables represent regions and demographic characteristics. Because agricultural and nonagricultural wages differ geographically (reflecting differences in labor demand and supply and the type of work), regional dummies are included in X_a and X_n . Years of schooling and years of experience are also hypothesized to influence wages and are included in X_a and X_n . Wages and the costs of working in agriculture may be affected by workers' racial and ethnic characteristics because of the discrimination or because they reflect language skills and legal status. They may, for similar reasons, also affect the costs of working in agriculture; hence they are included in X_a , X_n , and Z .

Also included is a dummy variable for "married, living with spouse," which has an ambiguous effect because married couples make joint employment and housing decisions. Given the relatively high variance in agricultural wage, one may be more willing to work in agriculture if one's spouse has a steady income; however, offsetting that effect, to the degree that migration is required in agricultural jobs, living with a spouse may be difficult. Similarly, having children may make migratory living relatively unattractive; however, whole families may work together in agriculture. Thus, marital status and children are included in Z , but their effects are also uncertain.

The reduced-form probit and the wage equations can be estimated without any further restrictions. The identifying restrictions that allow us to estimate the structural probit equation are that education and experience variables affect wages but do not affect the choice of sector except indirectly through their effects on the wage differential. Thus, in the structural probit, only other demographic characteristics and the wage differential are included. It is hard to justify why a year or two more of primary education would affect one's utility from working in agriculture rather than nonagriculture except indirectly through its effect on relative wages. It is similarly difficult to see why experience would affect utility directly; however, a case might be made that age (the experience variable is a lin-

ear function of age) affects utility differently in the two sectors. Not using the experience variables as identifying restrictions, however, has only a minor quantitative (and not a qualitative) effect on the results reported below.

The Data

Data used in this study are from the CPS for the 1988 calendar year, which is a random sample of individuals by housing units throughout the United States conducted monthly over the year.¹ Because selection is based on location, agricultural workers, nonagricultural workers, the unemployed, and documented and undocumented immigrants are surveyed.

The inhabitants of any given housing unit are asked questions about economic issues at two times, separated by a four-month interval. To prevent double-counting some workers (people initially interviewed in the first eight months of the year have a second interview in the same calendar year), only the first of these interviews is used. Only individuals at least sixteen years old, with no missing variables, who usually work at least fifteen hours per week (i.e., the employed), and earned at least \$2 an hour (to eliminate observations with implausible hourly earnings) were included.

Sample Restrictions

In the following analysis, the sample is restricted to only a subset of males who are relatively likely to consider agricultural employment: workers with no more than a ninth-grade education who live outside of major cities. Because less than 2% of all CPS workers are in

agriculture, the industry choice equation for the entire sample involves the tail of the sector-choice equation's error distribution; so the results are more sensitive to the choice of the error distribution (e.g., normal versus logistic) than if the mean were closer to the center of the distribution as reported below. Estimating a probit for all workers indicates that the only important determinant of agricultural employment is gender, and the estimated equation predicts (with nearly 99% accuracy) that everyone works in nonagriculture. The wage equations are not substantially different, however, if a larger sample is used.

Education was restricted because it would be a nonproductive exercise to calculate the wage differential necessary to induce a brain surgeon or other skilled worker to start working as an agricultural field hand. Although there are some hired farm workers who are highly educated (about one in 20 are college educated), the majority of agricultural workers have less than a high school education. The average number of years of education of seasonal agricultural workers is ten according to the CPS and seven according to the Department of Labor's National Agricultural Workers Survey for the same time period. The results reported below are not sensitive to the arbitrary ninth-grade cutoff. Similar qualitative results are obtained for thresholds at eighth grade, tenth grade, eleventh grade, and the twelfth grade (short of a diploma).²

Similarly, it is unlikely that workers in the middle of Manhattan are likely to switch to farm work with any plausible agricultural wage increase; so, because we are concerned with the short-run effect of a wage differential on choice of working in agriculture, the sample has been further restricted to those hired workers who live outside of major metropolitan areas with more than 100,000 people ("nonurban" areas). Although some agricultural workers with limited education live in cities, especially in California (e.g., Fresno), over two-thirds do not. Of workers with nine years or less of schooling, only one in ten works in agriculture of all workers compared to one in five of our nonurban sample.

¹ Some critics argue that the BLS undersamples migrant and illegal agricultural workers. Although this complaint may be valid, the CPS data set is used for four reasons. First, the CPS is the only random sample that includes both agricultural and nonagricultural workers in sufficient quantities to conduct a study of individual supply responses to wage differentials. Second, the included variable "Mexican" (as opposed to Mexican American, Chicano, or other Hispanic or non-Hispanic workers) is a proxy for legal status. This proxy is imperfect, however, because some of these Mexican workers may have legal status and others may misreport whether they are Mexicans. Third, if IRCA or other programs prevent undocumented aliens from working in agriculture, one would be primarily interested in the determinants of industry choices of workers with legal status. Fourth, the empirical study reported below was also estimated using only non-Hispanic workers, and the qualitative results for all equations and the quantitative results for the wage equations are virtually the same as those reported below. Thus, it seems unlikely that including more workers without legal status in the sample or including a variable for legal status would greatly change the results.

² It is unlikely that restricting our sample to relatively uneducated workers creates a sample selection bias for two reasons. First, in the short run, education must be viewed as a predetermined variable, and selecting on a predetermined variable does not cause a sample selection bias. Second, a Heckman sample selection test (based on a sample of all workers) does not indicate a sample-selection bias.

Females were dropped because there are not enough women in the sample to estimate an agricultural wage equation for females. There are only 396 females with 12 in agriculture (and more than 12 variables in the wage equations) in the sample. The effects of also including city dwellers and females are briefly discussed below.

Means and Standard Deviations

Presented in table 1 are the means and standard deviations (for continuous variables) of several key variables for our sample of 931 men, of whom 19.4% identified themselves as hired agricultural workers (including managers and fore-

men). The table also shows that more than a quarter (26.2%) of those in the sample live in the South Atlantic region, whereas only slightly more than a fifth (21.0%) of the agricultural workers live in that region. Similarly, where only 7.7% of the sampled live in the West (Pacific region), over a quarter (27.5%) of the agricultural workers live there. Moreover, only 5.7% of those in the total sample, but 27.1% of the agricultural workers, live in California.

Relatively more blacks and other nonwhites are in the agricultural subsample than in the overall sample. Agricultural workers are less likely to be married and living with their spouses than nonagricultural workers (52.5% vs. 77.9%), perhaps reflecting the migratory nature of many

agricultural jobs and the relative youth of agricultural workers.

Nonagricultural workers are, on average, seven years older than agricultural workers. Because the average level of education in the United States has risen over time, non-Hispanics with relatively little formal education tend to be older than the rest of the population. The average age of workers in agriculture is forty-two; the average age of non-Hispanics is forty-nine (and the median is 50), however, the average age of Hispanics is only thirty-five (and the median is 32).

Although 17.9% of the nonagricultural workers are union members, only 1.7% of the agricultural workers are union members (all of whom are in California). In this sample, agricultural workers average one fewer year of school than nonagricultural workers. Agricultural workers also have six years less work experience (calculated as age minus 6 minus years of formal school).

Many agricultural workers receive piece-rate payments (35% receive only piece rate compared to 11% of nonagricultural workers). In this study, hourly earnings are calculated by dividing the reported weekly earnings by the reported usual weekly hours. For workers who receive time rate pay, this calculated hourly earnings number is usually identical or very close to the reported wage. The average hourly earnings of agricultural workers (\$4.80) is only 62% of those of nonagricultural workers (\$7.69). They work, on average, 2.2 more hours a week, however, so that the average weekly earnings of agricultural workers are 66% of that of nonagricultural workers (\$203 versus \$308).

The Empirical Results

The first step of the analysis is to estimate a reduced-form probit equation describing how choice of industry depends on exogenous geographic and demographic variables. Then, conditional on industry choice, wage (hourly earnings) equations are estimated for each sector. Finally, a structural probit equation is estimated.

Reduced-Form Probit Equation

The reduced-form probit (working in agriculture = 1 and working in nonagriculture = 0) coefficient and asymptotic standard error estimates are shown in the second and third columns of table 2. Because it is a reduced-form equation,

the coefficients reflect both wage differential and cost factors as described above.

Compared to the West, living in the West North Central region makes one more likely to be in agriculture (all else the same). Similarly, Californians in the sample are much more likely to work in agriculture than others in the West.

An extra year of experience makes a worker more likely to work in agriculture if the individual has at least thirty-two years of experience (and less likely otherwise). In contrast, one more year of formal schooling makes one less likely to work in agriculture if one has had at least five years of schooling. Married men living with their spouses are less likely to be agricultural workers; however, the more children one has, the more likely one works in agriculture.

Workers who report their ethnicity as Mexican (as opposed to Mexican-American, Chicano, or other non-Mexican Hispanic or non-Hispanics) are much more likely to work in agriculture than other groups. Workers who report that they are non-Mexican Hispanics (including Mexican-Americans) are also more likely to work in agriculture than other groups but not as likely as the Mexicans.

The equation correctly predicts 87.3% of the observations. The various standard probit R^2 measures (Maddala, Hensher and Johnson, Chow) range from 0.29 to 0.46.³ A log-likelihood test strongly rejects the hypothesis that only the constant term matters.

Wage Equations

The wage equations (the regression of the natural logarithm of hourly earnings on demographic and geographic variables) in table 3 were estimated using Heckman's two-stage technique to control for nonrandom industry choice. The correlation between the disturbance in the regression and the selection criteria is very high (nearly one), and the estimates of the correlation are virtually the same for the two equations. On the basis of a Heckman t -test on the selectivity parameter, we can reject the hypothesis that ordinary least squares estimates have no sample selectivity bias in both the wage equations.

The equations show a different relationship in the two sectors with respect to geographic and

³ The probit equations and summary statistics were estimated using Kenneth J. White's Shazam program, version 6.1. The sample-selection adjusted wage equations reported below were estimated using William H. Greene's Limdep program, version 5.1.

demographic variables. In the nonagricultural sector, controlling for demographic characteristics, wages do not differ statistically significantly across regions or states with the sole exception that wages are higher in California. In contrast, regional differences in agricultural wages are pronounced. Compared to the West, wages are significantly lower in the New England, mid-Atlantic, East North Central, South Atlantic, East and West South Central, and Mountain regions. Surprisingly, in this sample, agricultural wages are lower in California than in the rest of the West, controlling for other factors. The wages in Texas are significantly lower than in the West.

At least for this relatively uneducated group, extra education does not statistically signifi-

cantly increase one's nonagricultural wage. In agriculture, however, extra education is positively related to wages up to five years of school but negatively for more years.⁴ Agricultural wage differences resulting from extra years of school are small (only a few pennies per hour), however.

At least until one has thirty-three years of experience, extra experience increases the non-agricultural wage; whereas, extra experience (or age) does not have a statistically significant effect on the agricultural wage. In the nonagricultural sector, having twenty years of experi-

⁴ Most previous studies based on the CPS (without educational limits on the sample) find that education does not have a statistically significant effect in the agricultural sector (e.g., Perloff) but does in the nonagricultural sector.

ence instead of ten is worth 18¢ more per hour.

In the nonagricultural sector, controlling for other factors, blacks earn 14% less per hour than whites; whereas there is no statistically significant wage differential between whites and other nonwhites or either group of Hispanics. In the agricultural sector, workers who report their ethnicity as Mexican earn 82% more an hour than whites; other Hispanics earn 65% more; and blacks earn 28% more.⁵ These cross-sector racial wage differentials may reflect either discrimination or other effects not otherwise captured by the exogenous variables in this equation.

For example, nonwhites and Hispanics may be more likely to work in jobs that pay premia, such as dangerous jobs or certain migrant jobs.

The qualitative results from these wage equations are similar to those of earlier studies (e.g., Perloff) that are based on CPS data but did not adjust for the sample selection effect of industry choice. The quantitative effects differ substantially, however. For example, in the wage equations shown above, the estimated ratio of wages in agriculture to those in nonagriculture averaged 31% over the sample. Based on estimates of the same equations using ordinary least squares, the comparable average wage ratio is 66%, or more than double, reflecting the failure to control for sample selection. Those people for whom the wage ratio is relatively high are more likely to work in agriculture as discussed next.

⁵ The unconditional mean hourly earnings by demographic group in agriculture are: all \$4.87 (with a standard error of 2.16), white 5.00 (2.14), black \$4.14 (2.13), Hispanic \$4.97 (1.70), and Mexican \$5.07 (1.68).

Structural Probit Equation

The structural probit equation is reported in the last two columns of table 2. To estimate it, the wage ratio, R , is approximated by the estimated difference in the natural logarithm of the wage one would earn in agriculture and in the non-agricultural sector.

In the structural probit equation, controlling for demographic and wage ratios, workers are more likely to work in agriculture in most other regions of the country than in the West. They are also more likely to work in agriculture in California than in the rest of the West. Of course, given that wage ratios vary geographically, much of the geographic difference in choice of sector is captured by the wage-ratio term.

The structural probit equation does not show a significant difference between choice of sector among whites and other racial or ethnic groups after controlling for wage ratios. That is, the preference of working in agriculture of these groups shown in the reduced-form equation is presumably captured in the structural equation by the wage-ratio term, which reflects relatively high agricultural wages for these groups.

The wage ratio has a large, statistically significant effect. A 1% increase in the relative wage in agriculture increases the probability that one works in agriculture by 3.37% at the sample mean. On average over the entire sample (Hensher and Johnson), a 1% increase in the relative agricultural wage increases the probability of working in agriculture by 1.3%.

The ratio of the estimated agricultural wage to the nongricultural wage is 0.37 for those workers in agriculture and only 0.30 for those who are not in agriculture. That is, the estimated wage ratio of those who choose to work in agriculture is nearly a quarter more than of those who choose not to work in agriculture. Thus, choosing to work in agriculture appears, in large part, to be based on a comparison of wages between the two sectors.

The structural probit has virtually the same explanatory power as the reduced-form equation. The probit R^2 measures range from 0.29 to 0.46; and the prediction success table shows that the correct sector is predicted for 87.5% of the sample.

Sensitivity Experiments

Other experiments were used to test the sensitivity of these results to the specifications used.

In none of these experiments was the key result (the effect of the wage ratio in the structural probit) substantially affected.

As a sensitivity test on the assumed error structure, the system was estimated using logit rather than probit equations (that is, the disturbances were modeled as logistic rather than normal). Although the key result was virtually the same as with the probit system, the correlation between the reduced-form logit equation and the selectivity equations' disturbance terms were estimated to be greater than one, which is, of course, impossible. For that reason, only the probit equations are reported here.

The system of equations reported above does not have a union variable on the right-hand side of any equation. Expanding this system of equations to include a union equation (with an error term that was correlated with the industry choice equation error term) and including a union dummy as an endogenous right-hand-side variable in the wage equations proved impossible to estimate (because of the very small number of union workers in the agricultural sector within this sample). Using the specification above but including union as an exogenous variable leaves the race and ethnicity coefficients in the wage equation virtually unaffected. As a result, union status was left to the residual term in the equations reported here. Alternatively this system may be viewed as quasi-reduced-form equations where the included demographic and regional (all the union members in the sample are in California) variables also explain union status.

As mentioned above, the results are not sensitive to the educational threshold. In another experiment, seasonal dummy variables (11 monthly dummies), which were included in all the equations, had coefficients that were not statistically significantly different from zero either individually or collectively in any equation. In yet another experiment, military veteran status was included in the probits. Although its coefficient was significant in the reduced-form probit, it is not included in the equations reported here because of its ambiguous interpretation. On the one hand, virtually all veterans have legal status (although the inverse does not hold); on the other hand, it may be a proxy for other factors such as intelligence or skills. Next, the dummy variable for non-Mexican Hispanic was divided into Mexican-American (or Chicano) and other Hispanics; however, these latter two variables had virtually identical coefficients.

Finally, a model was estimated using a larger sample that included city dwellers and females

but was still restricted to those with no more than nine years of education. Agricultural workers are only 6.6% of this larger sample. The same system was used except that a dummy variable for city and another for female were included on the right-hand side of all equations. Both these dummies had large, statistically significant effects in all equations; however, the other demographic coefficients were relatively unaffected. In the structural probit equation, the relative wage term remained large and had a *t*-statistic of 4.7. The predicted 4.4% shift into agriculture from a 1% increase in the relative wage at the sample mean is larger than in the model above. The original model is stressed in this paper because the estimates in the larger model are based on estimates in the tails of the normal (probit) distribution, which make inferences outside the sample, which we now examine, more speculative.

The Response to Higher Agricultural Wages

The system of equations can be used to simulate the effect of higher wages on the agricultural supply of nonurban, relatively uneducated workers. As shown in table 4, the estimated agricultural wage is only 29% of the estimated nonagricultural wage when averaged across the sample. The simulations reflect the effects of an across-the-board increase in the agricultural wage holding the nonagricultural wage constant. That is, the simulations increase the constant term in the regression on the logarithm of the agricultural wage, which is equivalent to a constant percentage increase in the agricultural wage for all workers.

In table 4, two methods are used to calculate

Table 4. Effect of an Increase in the Agricultural Wage

Increase in the Agricultural Wage (%)	w_a/w_n (%)	Percent Agricultural Workers	
		50% Rule	Average
0.00	29.38	10.63	19.45
2.00	30.04	10.96	20.07
4.00	30.63	11.82	20.69
6.00	31.21	12.35	21.31
8.00	31.80	12.78	21.94
10.00	32.39	13.10	22.57
20.00	35.34	15.47	25.76
30.00	38.28	18.69	28.96
40.00	41.23	21.91	32.15
50.00	44.17	25.35	35.30

the effect of the wage increase on the share of workers in agriculture as both are commonly used in probit studies. In the first method, a worker is assigned to the agricultural sector if the probability he works in agriculture (according to the structural probit equation) is at least 50%. Using this 50% rule, the model predicts that 11% of the workers will work in agriculture. In the second method, the probability of working in agriculture that the model predicts for each individual is averaged across all individuals (using equal weights). This average is 19%, which is (by the nature of the probit estimation technique) virtually the same as the actual percentage in the sample.

If the agricultural wage increased by 2%, the wage ratio would increase by 2.2%. Using the 50% rule, the share of workers in agriculture would increase by 3.1% (or 0.33 percentage points from 10.63% to 10.96%; whereas, using the second method, the share would increase by 3.2% (or 0.62 percentage points from 19.5% to 20.07%). If the agricultural wage were raised by 10% (with no response in the nonagricultural wage), the first method indicates a 23% increase in the share of agricultural workers; the second method predicts a 16% increase.

Simulations of larger wage increases should, of course, be viewed with substantial caution. If the point estimates are assumed to hold with larger increases, a 50% increase in the agricultural wage leads to a 139% increase in the share of agricultural workers using the first method (to a quarter of this relatively uneducated labor force) and an 82% increase using the second method.

In interpreting these simulations, recall that they reflect a national average for nonurban, relatively uneducated workers. There may also be (a presumably smaller) response by better educated or urban workers. Thus, the simulations reported here may be lower bounds on the true (larger) response. However, if IRCA were strictly enforced, driving undocumented workers out of agriculture, a substantial number of U.S. citizens and immigrants with legal documentation would have to be hired to replace them. One survey of California employers (Rosenberg and Perloff) indicates that in 1987, after the passage of IRCA, one-third of new hires were illegal aliens.

Conclusions

This paper presents a model of industry choice and wage determination. The chief result of this

analysis is that inducing more workers to switch to agriculture may not require large wage increases. Indeed, a 10% increase in wages may increase the share in agriculture of nonurban male workers with no more than a ninth-grade education by nearly a quarter. Nonetheless, in some states and in certain crops, half or two-thirds of the agricultural work force has been undocumented aliens so that larger wage increases may be required. Because this study has focused on only supply-side effects, a full analysis of the wage effects of a government policy that prevented undocumented workers from working requires a comparable demand-side analysis.

Further work on agricultural labor supply remains to be done as well. For example, this report has focused on the role of higher wages in attracting agricultural labor. In general, however, better working conditions and other benefits (such as health insurance and housing) could also attract extra workers, holding wages constant.

Labor Contracting and a Theory of Contract Choice in California Agriculture

Ann Vandeman, Elisabeth Sadoulet, and Alain de Janvry

We present a model of labor contracts, where seasonality, the sensitivity of output to labor quality and work intensity, and the relative advantages of labor contractors in recruitment and growers in supervision of seasonal farm workers determine the choice of employment contract. Differences in the optimal means of extracting work result in lower wages paid under labor contracting than direct hiring. We derive and estimate the probability of labor contracting and wages as functions of worker and job characteristics using data on California farm workers and employers. From estimated expected wages, our results indicate that successful unionization or reducing the flow of undocumented workers into California agriculture both would reduce contracting and increase wages.

Key words: agricultural labor, contract theory, labor contracting, sample selection bias.

Labor contracting is an old institution in California agriculture. Contractors have supplied crews to plant, hoe, thin, and harvest labor-intensive fruit and vegetable crops in the state for more than 100 years. It is also a persistent institution. Although advocates of farm labor unionization predicted that contracting would disappear with the introduction of collective bargaining, contractors have continued to increase their share of the seasonal labor market. Currently, about one-third of the production jobs on California farms are performed by workers supplied by contractors. How contractors contribute to the functioning of the labor market and to management of the labor process are the subjects of this paper.

Labor contractors are independent intermediaries who, for a fee, recruit, hire, and supervise seasonal farm workers. Their work force is composed primarily of immigrant workers with limited knowledge of their rights or ability to exercise them. Workers are often dependent on

the contractor for transportation, housing, and access to health care in addition to a paycheck. High levels of unemployment among these workers, resulting from labor demand seasonality and from the constant replenishment of the labor pool through immigration, foster this dependence. Abuse of this relationship has resulted in a rather unsavory reputation for contractors (Vaupel and Martin). Accounts of promised jobs that do not materialize; wages not paid; and overcharging for transportation, food, and housing are common. Growers also fall victim to abusive contractors who pad the payroll with phantom workers or exaggerate production figures. Reports of fraud and abuse led California to require licensing and bonding of contractors in 1939. Federal law followed suit in 1963.

What accounts for the persistence of this antiquated and apparently primitive institution in agriculture? Contractors were used originally to bring Chinese immigrant workers into agriculture, where lack of a common language was a barrier to direct employment and supervision (Fisher). Today, most foremen and field supervisors, and many growers themselves, are bilingual. Thus, while the work force still is composed primarily of immigrant workers, language is no longer a barrier between employer and employee.

Economic analyses of the labor process have sought to explain patterns in the organization of agricultural production by applying the theory

Giannini Foundation Paper No. 987.

The authors wish to thank two anonymous reviewers for helpful comments on an earlier version of this paper. The paper is an outgrowth of the first author's Ph.D. thesis, which was supported by the Giannini Foundation, the Senator Drobish Memorial Endowment Fund, and the Department of Agricultural and Resource Economics, University of California, Berkeley.

of transactions costs to particular problems of tenancy and labor contract choice, such as the payment of piece versus time rates (Stiglitz, Roumasset and Uy), permanent versus casual labor contracts (Bardhan, Eswaran and Kotwal 1985b), and alternative forms of tenancy (Eswaran and Kotwal 1985a). We employ this theory to examine the unique role of the contracting system in labor-intensive agriculture.

Previous studies of seasonal farm labor have identified labor demand seasonality as the source of low returns to farm work and problems of unstable labor supply (e.g., Holt, p. 11). We argue that the contracting system is advantageous to growers precisely because it preserves the casual nature of seasonal farm work. Contractors possess an advantage in recruiting workers for seasonal jobs because they can spread their recruitment costs over a number of short-term contracts. They are also more efficient than growers in the recruitment of new entrants to farm work, workers with little knowledge of the farm labor market or labor standards, and workers whose alternatives inside and outside of farm work are limited by their illegal status. We will show that hiring workers with these characteristics enables contractors to achieve higher levels of work intensity in certain types of jobs while paying lower wages than growers who hire labor services directly.

Contracting is, however, not appropriate to meet all of agriculture's labor needs. In particular, growers have an advantage in direct hiring for jobs which are less seasonal and which require greater care and knowledge of production.

In the next section we develop a formal model of the grower's contract decision and wage determination, where the contract alternatives are direct hiring and contracting for labor. The model is used to infer a distribution of contracts across types of jobs. Then we reverse the use of the model to derive the conditional distribution of workers between contract types in a given job and the predicted wages expressed as a function of contract type. Subsequent sections present empirical results for these two equations and use these results to calculate expected wages under alternative policy scenarios.

Labor Contracts and Labor Extraction

The functions of the contracting system are considered at two levels: in the labor market and within the labor process. Labor market functions include the recruitment and hiring of

workers. In the labor process, the objective is to induce workers to work at some optimal level of effort and quality.

The grower has two basic alternative means of access to labor: direct hiring and management of workers and purchasing labor from a labor contractor. Growers are assumed to make decisions on these alternatives at each stage of the production process of each crop, and each decision is assumed independent. Thus, they may choose to employ labor directly for one task and to contract for labor at a later stage of production. The choice of contract will depend on the activity to be performed and on the relative efficiencies of growers and labor contractors in the recruitment of workers and the extraction of work in that particular activity.

Supervision and the Cost of Job Loss

Growers and contractors have two means of extracting work from workers. One is by direct supervision, which primarily influences the quality of the work, and the other is to apply pressure to increase the quantity of work by the threat of job loss.

Supervision involves directing and coordinating the labor process; making the day-to-day production decisions regarding the time and levels of input use, including labor inputs, and their methods of application. The effectiveness of supervision depends upon the supervisor's ability to manage production. The importance of supervision to an activity, whether it be pruning vines, applying fertilizer, or harvesting garlic, will vary with the sensitivity of output quality to the labor process.

Growers have a comparative advantage in supervision over contractors because of their greater knowledge of the production process. The grower's proprietary interest in maintaining the yield potential of fixed inputs such as land, trees and vines, and in protecting investments in equipment, also gives him greater incentive to supervise effectively those activities requiring greater care. Let S be the cost of supervision per unit of labor time and γ_i a parameter representing the efficiency of supervision under contract i . Because growers are relatively more efficient in supervision than contractors, $\gamma_d > \gamma_c$ (throughout, we use $i = d$ for direct hiring and $i = c$ for contracting labor).

Employers can also affect work effort by controlling the cost of job loss, defined as the difference between the actual wage and the work-

er's opportunity wage (Shapiro and Stiglitz, Bowles). The cost of job loss affects work effort (Becker and Stigler, Stiglitz). The threat of job loss is more effective, and hence effort increases, the greater is the cost of job loss that the employer can impose on the worker. Thus, high costs of job loss are implied by the common observation that farm workers work "hard and scared." Compared to direct supervision, this indirect control of the worker's performance is more useful in influencing the quantity of work rather than the quality of work. We discuss the components and manipulation of the cost of job loss in more detail at the end of this section.

Given the other inputs, the output of each activity is a function of labor time, L , modified by the level of supervision, and by the work effort E , which is influenced by the cost of job loss. Let $\alpha_2(j)$ and $\alpha_3(j)$ represent the importance of labor time and supervision to the output of activity j . For a given contract type i , the output of activity j is

$$(1) \quad Q_{ji} = E_{ji}(\gamma_i S)^{\alpha_3(j)} L^{\alpha_2(j)},$$

where E_{ji} represents the average level of work effort among the workers hired which is affected by the cost of job loss.

The cost of job loss to a worker is the difference between two components: the actual wage paid and the opportunity wage of that worker. Therefore, employers can increase the cost of job loss by recruiting workers with low opportunity cost, or by increasing their wage. However, both of these actions, recruitment and wage strategies, are not done selectively for individual workers but apply to the whole pool of workers. The employer chooses an overall strategy of recruitment that will give him access to a certain pool of workers from which he will hire, applying no further selection among the individuals. Similarly, he chooses an overall level of incentive bonus on the wage, which is then applied to the structure of individual wages. Because workers in the recruited pool are not homogenous, their individual wages, opportunity costs, and work efforts will differ. The outcome of the recruitment and wage policies will then be measured by an average intensity of work among the pool of recruited workers. We discuss the recruitment and wage policy before aggregating them in an average level of work intensity.

Because a worker's opportunity wage is determined in part by his or her individual characteristics, employers can manipulate the cost of job loss by targeting groups of workers with

particular characteristics for recruitment and hiring. Let X be a vector of characteristics describing the worker, R be the per worker cost of recruitment, and δ_i be the relative efficiency of recruitment under contract i . The level of recruitment expenditure determines the pool from which workers are hired. The pool is identified by a frequency distribution of characteristics $f(X; \delta_i R)$. It may consist of a local community of settled farm workers, a migrant stream within the United States, a cross-border migration network, or a combination of these groups.

Farm labor contractors specialize in the delivery and management of seasonal labor. This gives them two advantages. First, their more extensive contacts within farm worker communities and migration networks provide them greater access to those segments of the labor force with lower average opportunity wages, consisting of high proportions of undocumented workers, nonunion workers, and workers with little or no experience in the U.S. farm labor market. Their second advantage is the ability to reduce recruitment costs per unit of labor time by spreading these costs over several contracts. Because contractors are relatively more efficient in recruitment, $\delta_c > \delta_d$.

The second means of increasing the cost of job loss is to increase the wage. High unemployment in farm work, because of seasonality and the constant influx of new immigrant workers, precludes an assumption of competitively determined wages in this market. Thus employers exercise some control over wage rates above the federal minimum wage. Growers have both greater flexibility and face greater pressure to use wage incentives. Competition for contracts reduces the possibility for contractors to use a positive wage incentive to extract higher levels of work effort. Growers also face a greater union threat and, because unionization reduces the risk of job loss, greater pressure to increase wages in order to maintain the effort incentive (Rebitzer, Schor and Bowles). They are identified with fields that can be picketed and in some cases with a product susceptible to boycott. In contrast, contractors have not been successfully unionized, and their mobility and lack of capital make it virtually impossible to enforce collective bargaining agreements. These were, in fact, the arguments made to exclude contractors from collective bargaining legislation.

The determination of the wage and the cost of job loss are specified formally in the following way. Let w_0 be the prevailing minimum wage rate for farm work. The actual wage paid by an

employer to a worker X is $w_{og}(X, B)^{\varepsilon_i}$, where $g(X, B)^{\varepsilon_i}$ is the ratio of the actual wage to the minimum wage for workers X and contract type i . This ratio is a function of three components: X , the vector of worker characteristics; B , the average wage bonus for the labor pool; and ε_i , the parameter representing the difference in wage flexibility and pressure under the two contract types. The greater wage flexibility and the greater pressure to increase wages under direct hiring imply that $\varepsilon_d > \varepsilon_c$.

The worker's opportunity wage is expressed as a function of individual characteristics and contract type, $w_i^*(X)$. Opportunity wages will vary by contract type because of differences in the hiring preferences of growers and contractors. For instance, unionized workers have a higher opportunity wage under direct hiring as they benefit from the union's bargaining power but a lower opportunity wage under contracting as growers explicitly seek nonunionized workers when obtaining workers through a labor contractor. The cost of job loss for the individual worker X is

$$(2) \quad C_i = w_{og}(X, B)^{\varepsilon_i} - w_i^*(X).$$

Aggregating over the pool of workers, levels of R and B in a given activity j and contract type i produce the following average labor effort:

$$(3) \quad E_{ji} = \int_x [w_{og}(X, B)^{\varepsilon_i} - w_i^*(X)]^{\alpha_1(j)} f(X; \delta_i R) dX.$$

The parameter $\alpha_1(j)$ represents the impact of work effort on the output of activity j .

The concept of the cost of job loss provides a link between the contractor's roles in the labor market and the labor process. The contractor's ability to recruit and hire workers with limited employment alternatives facilitates the process of labor extraction by increasing the average cost of job loss and, therefore, work effort.

Choice of Contract

Thus, the choices of four variables determine the proceeds and the costs of labor in the considered activity: (a) the level of employment L , (b) a supervision cost per unit of labor S , (c) a recruitment cost per worker R , and (d) an average wage bonus B . The proceeds of work are measured by the production of activity j under contract i :

$$(4) \quad Q_{ji} = \int_x [w_{og}(X, B)^{\varepsilon_i} - w_i^*(X)]^{\alpha_1(j)} f(X; \delta_i R) dX \cdot (\gamma_i S)^{\alpha_3(j)} L^{\alpha_2(j)}.$$

The average wage of the pool of workers hired under contract i is

$$(5) \quad \bar{w}_i = \int_x w_{og}(X, B)^{\varepsilon_i} f(X; \delta_i R) dX.$$

The overall cost of labor, including supervision and recruitment, is

$$(6) \quad [\bar{w}_i + S + R/\alpha_4(j)]L,$$

where the quantity $R/\alpha_4(j)$ is the recruitment cost per unit of labor time and $\alpha_4(j)$ is the average length of job j .

Under direct hiring, the grower takes all the decisions and will choose levels of L , S , R , and B that maximize his profit:

$$\text{Max}_{L,S,R,B} \Pi_{dj} = p_j Q_{dj} - (\bar{w}_d + S + R/\alpha_4(j))L.$$

Under a common form of indirect contracts, these decisions are taken by the contractor who is paid a fixed fee for a given task. His objective function in deciding on levels of L , S , R , and B is to minimize the overall labor costs, including recruitment and supervision, to perform the task \bar{Q}_j specified by the grower:

$$\begin{cases} \text{Min}_{L,S,R,B} (\bar{w}_c + S + R/\alpha_4(j))L, \\ \text{s.t. } Q_{cj} = \bar{Q}_j. \end{cases}$$

Competition among contractors ensures that their fees are set to cover just their costs, equal to the sum of the labor costs, and a nominal fee for their service. This leaves the grower with a profit:

$$\Pi_{cj} = p_j \bar{Q}_j - (\bar{w}_c + S + R/\alpha_4(j))L - \overline{CF},$$

where \overline{CF} is the contractor's service fee, and L , S , R , and B are set at their optimal levels.

As the contractor's cost-minimizing problem is formally equivalent to a profit-maximizing problem, the optimal choice of L , S , R , and B under contracting can also be written as a solution of the grower's profit maximization problem:

$$\text{Max}_{L,S,R,B} \Pi_{cj} = p_j Q_{cj} - (\bar{w}_c + S + R/\alpha_4(j))L - \overline{CF},$$

with the decision taken, however, by the contractor with his comparative characteristics ε_c , w_c^* , δ_c , and γ_c .

The final decision as to which of these contracts will be used in the hiring of labor rests on the grower, who chooses the contract which yields him the highest profit. In a world of certainty, with identical growers, the same optimal contract will always be chosen for the same activity. However, in the real world of differentiated growers, the profitability of a given contract is not identical for all growers and, thus, neither is the optimal contract. In fact, we observe a distribution of contracts for each activity, not a unique dominant contract. This distribution of contracts is analyzed next.

The Distribution of Contracts by Job Types

Let $\bar{\pi}_i$ be the expected maximum profit for contract i in a given activity (the activity subscript j is omitted). Because growers differ in management ability, their profit expectations will be distributed around $\bar{\pi}_i$. Thus, any particular grower's contract choice will be based on his expected profits expressed as

$$(6) \quad \pi_i = \bar{\pi}_i + u_i,$$

where u_d and u_c are random variables. The probability that a grower chosen at random will choose contract c is

$$(7) \quad P(c) = P(u < \bar{\pi}_c - \bar{\pi}_d),$$

which is equal to the value of the cumulative distribution of u at $(\bar{\pi}_c - \bar{\pi}_d)$, or $F(\bar{\pi}_c - \bar{\pi}_d)$. Profits are calculated for each activity, so the characteristics of the job—the importance of the quality and quantity of labor to output—ultimately determine which contract is chosen.

In this empirical analysis, the data are from a

statewide survey of farm workers conducted in 1983 (Mines and Martin). The survey sample is made up of an aggregation of samples chosen from agricultural areas served by forty-two job service center offices in California. The interviewers, job service employees who regularly work with agricultural employers and farm workers in these offices, constructed quotas for sampling within their office jurisdictions based on their knowledge of the area and on guidelines developed by the survey team. Criteria were location, ethnicity, household composition (insuring a minimum number of interviews with single person households), sex, and job type (insuring a minimum number of interviews with irrigators and equipment operators). Respondents were fourteen years of age or older, household heads or spouses, and had worked at least twenty-five days in farm work during the twenty-four months prior to the survey date. Employer type was not a criterion for sample selection. Although the sample is not random, the sample selection process should not bias the results on the distribution of jobs, workers, and wages by contract type. Only observations on workers employed in nonsupervisory positions in their current job by either a labor contractor or a grower are included. Foremen, those working in off-farm jobs, and those employed by a packing house or sharecropper at the time of the interview were excluded from the sample. The latter two types of contracts cover only a small fraction of jobs and are restricted to particular crops and regions.

Table 1 illustrates the effects of job type on contract choice among growers in California. Overall, 28% of the jobs in this sample were performed by contract labor. Contracting ac-

Table 1. The Distribution of Contracts by Job Type and Average Job Length for Agricultural Jobs in California, 1983 Sample

Job	Direct Hiring		Contracting		Average Job Length Weeks
	Number	(%)	Number	(%)	
Harvest	290	65.2	155	34.8	11.5
Prune	53	84.1	10	15.9	12.7
Thin	14	82.4	3	17.6	16.8

counts for 35% of all harvesting jobs, 50% of hoeing (weeding and thinning row crops), and 30% of sorting. In contrast, growers hire directly for over 90% of all irrigator and machine operator positions.

Two factors are at work in determining this distribution of contracts. First, where the payoff to supervision is high because of the key role of work quality, as in irrigating or operating machinery, more direct hiring is observed. Where work intensity has the greater effect on output, as in the most routine and repetitive tasks, contract hiring is more prevalent. Timing and the effect of recruitment costs on contract choice also are evident in these results. Growers more often contract out the short season jobs, such as harvesting and sorting, where their unit costs of direct recruitment and hiring are greatest. The lower unit costs of recruitment and hiring in more permanent positions are thus another reason we see growers directly hiring most irrigators and machine operators.

The Distribution of Workers between Contract Types

The fact that, for a given activity, there is both direct hiring and contract hiring means the same task could be performed by the same worker under either one of the contracts. However, with different comparative advantages in recruitment and supervision, we have seen that growers and contractors do not recruit from the same pools of workers. For that reason, some workers are more likely to be hired directly and others to work under labor contractors. The resulting distribution of workers between the two contracts is now examined. As will be shown, it depends not only on the type of job but also on individual characteristics that determine the pool from which the worker is most likely to be recruited.

For a given job j , if contract i is chosen and R and B are set at their optimum levels, then the distribution of workers hired under that contract is $f(X|i, j)$. The total distribution of workers for a given activity j is

$$(9) \quad f(X|j) = [1 - F(\bar{\pi}_c - \bar{\pi}_d)]f(X|h, j) + F(\bar{\pi}_c - \bar{\pi}_d)f(X|c, j).$$

The probability that a worker selected at random from a given activity and with characteristics X is hired under a labor contractor is

$$(10) \quad f(c|X, j) = f(X|c, j)F(\bar{\pi}_c - \bar{\pi}_d)/f(X|j).$$

For a given job j and worker k , these probabilities are dependent on the characteristics $\alpha(j)$ of the j th job and the characteristics X of the k th worker. The distributions depend on the job specifications because of their effect on the relative profitability of the two contract types and, hence, on the choice of contract. They also depend on the worker's characteristics because of the differences in the optimal levels of recruitment and in the relative efficiencies of recruitment between contracts. Finally, these distributions depend on the relative efficiency of supervision and use of the wage incentive by growers and labor contractors. Therefore, the reduced form for the probability of contract i is

$$(11) \quad f(i|X, j) = h(X, \alpha(j)),$$

where $\alpha(j) = [\alpha_1(j), \alpha_2(j), \alpha_3(j), \alpha_4(j)]$ is a vector of characteristics of activity j .

Wages are also endogenous and jointly determined along with the choice of contract as a function of job type and worker characteristics. The theoretical form was written $w_{og}(X, B)^{e_i}$, where B , set at its optimal level, depends on the $\alpha(j)$ and on the contract characteristics $\beta(i) = [\varepsilon_i, w_i^*(X), \delta_i, \gamma_i]$. Hence, a reduced-form expression for wages is

$$(12) \quad w = f[\alpha(j), X, \beta(i)].$$

Because the cost of job loss is defined as the difference between the wage paid and the opportunity wage, observed wages should increase with opportunity wages which depend on alternative sources of wage and nonwage income and on the contract type. Wages should be relatively higher in direct hiring, where recruitment costs are higher and the threat of unionization reduces the cost of job loss.

Econometric Results

We now turn to the estimation of the reduced-form equations for the probability of labor contracting and for the wage and to the empirical verification of the assertions derived from the theoretical model. Probit approximations of the distribution of contracts (11) and linear approximation of the wage (12) are as follows:

$$(13) \quad LC_h^* = a_1Z_j + b_1X_k + c_1N_r + u_h,$$

$$(14) \quad P(LC_h = 1) = \Phi(LC_h^*), \text{ and}$$

$$(15) \quad w_h = a_2Z_j + b_2X_k + c_2N_r + eLC_h + v_h,$$

where LC_h^* is a nonobservable criterion function

for selection of the worker k , in job j , and region r by a labor contractor ($h = [j, k, r]$ is an index of the observation), LC_h is a dummy variable equal to 1 if, in the observation h , hiring is done through a labor contractor and 0 if there is direct hiring, Φ the cumulative normal density function, w_h is the wage, Z_j is a vector of job specifications, X_k is a vector describing the worker's characteristics, and N_r is a vector of regional variables. The random variables u_h and v_h are assumed distributed normally with zero mean and variance $\sigma_u^2 = 1$ and σ_v^2 , respectively.

Table 2 contains a complete list of the variables used to estimate the model and their definitions, taken from the farm worker survey data referred to above. The personal characteristics variables included in the model are sex, years of farm work experience in the United States, union membership, legal status, and migrancy status. The number of years of farm work in the

United States captures the accumulated knowledge of the U.S. farm labor market, where and how to get jobs, the wage structure, and employee rights. It is not meant to measure any qualification that would influence the productivity of the worker because such qualification requirements do not differ significantly among the types of jobs considered in this study.

Ideally, the vector of job characteristics would include a duration variable and indices for the relative importance of labor quality (supervision) and quantity (work effort) in each crop and task. However, the information available from this and other similar surveys is not sufficient to construct the necessary variables. For example, the survey data on job length are right-censored at the interview date in every case. Therefore, dummies were used for the crops and tasks. The job types included in the model are harvesting jobs, pruning, hoeing, irrigating, sorting, and machine operation. Job effects are

Table 2. Variable Definitions

Dependent variables

Wage rate:	the hourly wage rate for the worker (hourly earning for piece rate jobs).
LC:	a dummy variable for contract type = 1 if the worker is employed by a labor contractor, 0 if he or she is employed directly by a grower.

Worker characteristics (X)

Sex:	a dummy variable = 1 for males, 0 for females.
U.S. farm work experience:	years of farm work experience in the United States.
Union membership:	a dummy variable for union membership = 1 if the worker has been a union member in the last 3 years, 0 if not.
Illegal status:	a dummy variable = 1 if the worker is undocumented, 0 if he or she is legally working in the United States.
Migrant:	a dummy variable for migrancy status = 1 if the worker is away from home on his/her current job, 0 if not.

Job specifications (Z)

Harvest citrus:	a dummy variable = 1 for citrus harvesting jobs, 0 otherwise.
Harvest grape:	a dummy variable = 1 for grape harvesting jobs, 0 otherwise.
Harvest vegetable:	a dummy variable = 1 for vegetable harvesting jobs, 0 otherwise.
Harvest field fruit:	a dummy variable = 1 for field fruit harvesting jobs, such as strawberries or melons, 0 otherwise.
Prune vines:	a dummy variable = 1 if the job is pruning vines, 0 otherwise.
Hoe:	a dummy variable = 1 if the job is hoeing, all crops, 0 otherwise.
Irrigate:	a dummy variable = 1 if the job is irrigating, all crops, 0 otherwise.
Sort:	a dummy variable = 1 if the job is sorting, all crops, 0 otherwise.
Machine operator:	a dummy variable = 1 for machine operator jobs, all crops, 0 otherwise.
Time rate:	a dummy variable = 1 if the worker is paid by the hour, 0 if by the piece.
Peak employment:	a dummy variable = 1 if worker's employer hires more than 50 workers at peak, 0 otherwise.

Regions (N)

Southern California:	a regional dummy variable = 1 for workers in Southern California (including Los Angeles, San Bernardino, Orange, Riverside, San Diego, and Imperial Counties), 0 otherwise.
Coastal region:	a regional dummy variable = 1 for workers in the Coastal Region (including Contra Costa, Alameda, San Mateo, Santa Cruz, Santa Clara, San Benito, Monterey, San Luis Obispo, Santa Barbara, and Ventura Counties), 0 otherwise.
Sacramento Valley:	a regional dummy variable = 1 for workers in the Sacramento Valley (including Sacramento, Yolo, Yuba, Sutter, Colusa, Butte, Glenn, and Tehama Counties), 0 otherwise.

compared to the deciduous fruit harvest. The jobs requiring greater care in their performance and, hence, greater supervision are pruning, equipment operation, and irrigating. These jobs also last longer than other farm jobs. For these reasons, growers should find it more profitable to fill these positions through direct hiring. In contrast, because work intensity is the primary factor determining output in most harvesting operations, a higher probability of contractor employment is expected in these jobs, with some variation between crops as a function of job length and quality effects on output. Peak employment is included in the model to account for variation in the levels of union threat and recruitment cost per worker by farm size.

The method of payment follows from the grower's choice of crop and is, therefore, exogenous. Piece rates are used in jobs where work intensity is critical to output; thus, we expect the probability of contracting to be positively related to piece rate work. If piece rates also serve as a screening device (Stiglitz), then piece work should yield higher hourly earnings as the more productive workers will choose these jobs. But the gains may not be equal for workers under both contracts. Piece rate earnings are dependent in part on crop yield, and there likely is a tendency to employ contract labor in the least productive piece work positions. Suppose, then, that fields can be divided into high yield and low yield. We would expect a greater increase in earnings over hourly rate jobs in the high yield fields. However, we do not observe yield differences, only that high yield is usually directly hired and low yield usually contracted. Therefore, the difference in productivity is captured by including an interactive term for the method of payment variable (LC^* time rate).

Interaction terms also are included in the wage equation to allow the effects of worker characteristics on wages to vary by contract type. The effects will not be equal where these characteristics are viewed differently by growers and labor contractors [$w_i^*(X)$ in equation (2)].

Regional effects are normalized on the Central Valley and include dummies for Southern California, the coastal region, and the Sacramento Valley. These variables represent regional differences in recruitment costs, the effect of crop mix on labor demand seasonality, and regional variation in the influence of labor unions.

Estimation results are reported in table 3. The estimated effects of U.S. farm work experience, legal status, and union membership on the prob-

ability of contract employment (column 1) are all consistent with the theoretical model. Undocumented workers are more likely to be employed by a contractor than directly by a grower. The contractor is better able to channel undocumented workers into the farm labor market and to absorb the cost of replacing workers who are picked up and deported. Under the new sanctions against hiring undocumented workers imposed by the Immigration Reform and Control Act of 1986, we may see increasing numbers of growers choosing to contract rather than risking the cost of violation.

Union membership has a significant negative effect on the probability of contractor employment. Union members are entitled to job placement services and exclusive rights to jobs covered by union contract. Then the question is, why would union members work for contractors? Although unions provide some job security, union jobs make up only a small fraction of all farm jobs, and they are subject to the seasonality of labor demand. Therefore, union workers may choose employment with a contractor over unemployment during seasonal layoffs.

Crop/task variables distinguish labor requirements by seasonality, work quality, and optimal work intensity. The negative and significant coefficients for irrigators and machine operators confirm that growers are more likely to hire directly for jobs requiring more supervision. Positive coefficients for hoeing and vegetable harvesting are also consistent with the hypothesized effects of work quality and timing on labor demand decisions. Hoeing row crops is unskilled work performed intermittently during the growing season, and vegetable harvesting is a short-season task emphasizing work intensity in most crops. Citrus harvesting is a long-season task where quality is relatively important; yet, it is more likely to be contracted. This may reflect growers' reaction to union organizing in citrus. Many growers withdrew from the commodity associations whose members were bound by union contracts won in the late 1970s and substituted much cheaper contract labor (Mines and Anzaldúa).

The Wage Equation

We have argued that the grower's choice of contract is endogenous. Because both this decision and wage rates are dependent on the same set of characteristics, any omission or measurement

error in these characteristics may lead to a correlation of the error terms u and v . This would, in particular, introduce a bias in the wage equation as

$$\begin{aligned} E(w_h|LC_h = 1) &= a_2Z_j + (b_2 + b'_2)X_k \\ &\quad + c_2N_r + e + \sigma_{uv} \frac{\varphi}{\Phi}, \text{ and} \\ E(w_h|LC_h = 0) &= a_2Z_j + b_2X_k + c_2N_r \\ &\quad - \sigma_{uv} \frac{\varphi}{1 - \Phi}, \end{aligned}$$

in which ϕ and Φ are the density and cumulative normal distribution evaluated for the estimated value of the criterion function LC_h^* , and σ_{uv} is the covariance of u and v . Testing and correction for this potential selection bias is done by following the Heckman method (Maddala). It consists of an OLS estimation of an extended wage equation:

$$\begin{aligned} w_h &= a_2Z_j + (b_2 + b'_2LC_h)X_k \\ &\quad + c_2N_r + eLC_h + \sigma_{uv}\lambda + \varepsilon, \end{aligned}$$

in which λ is the Inverse Mill's Ratio, equal to ϕ/Φ or $-\phi/(1 - \Phi)$, and ε is an unbiased normal error term.

The results of the wage equation appear in column 2 of table 3. Column 3 contains derived estimates for the total effects of variables on wages under contracting. The signs of the coefficients are consistent with the model, and some significant differences occur in the determination of grower and contractor wages. Thus, the wage difference by gender in direct hiring disappears under contracting. U.S. farm work experience has a small but significant negative effect only on contract wages, and the positive effect of union affiliation under direct hiring becomes significantly negative under contracting. Legal status and migrancy do not appear to affect wage rates under either contract.

As expected, larger employers pay slightly higher wages, and the piece rate differential is larger under direct hiring. We believe the latter results from direct hiring for the most productive piece work jobs and contracting others. Some self-selection into direct hire piece work may also be involved in producing this result.

Somewhat surprisingly, net wage differences are not significant in irrigating and machine operator positions, where supervision has a greater effect on output and direct hiring dominates. The prevalence of direct hiring itself may explain the higher wages observed in these jobs. On the other

hand, wages are significantly higher in citrus, vegetable harvesting, hoeing, and sorting, activities in which work effort has a greater effect on output and unions have had some impact. Thus, in a given contract, the importance of work effort does appear to increase use of the wage incentive. Wages are higher in the Coast region, where high value vegetable crops are grown under the control of a relatively few large produce companies and unionization has been relatively successful. Wages in the Sacramento Valley, by contrast, are lower than in the Central Valley.

The average wage for all workers with given qualifications and on a given job is

$$\begin{aligned} (16) \quad E(w_h) &= a_2Z_j + (b_2 + b'_2\Phi)X_k \\ &\quad + c_2N_r + e\Phi, \end{aligned}$$

which shows the two components of the effect of labor contracting on the wage. The term $b'_2\Phi$ captures the difference in opportunity cost of a given worker X_k under contractor and grower hiring. The last term measures an additional impact varying with the probability of being hired by a contractor from 0 to the maximum value of $e = -3.38$ dollars.

This last effect comes from the difference between the wages paid to workers with the same qualifications in the same job under the two contracts:

$$\begin{aligned} E(w_h|LC_h = 1) - E(w_h|LC_h = 0) \\ = b'_2X_k + e + \sigma_{uv} \frac{\varphi}{\Phi(1 - \Phi)}. \end{aligned}$$

The coefficient e is thus an overevaluation of the negative impact of the labor contracting system if σ_{uv} is positive, and an underevaluation if the correlation is negative. Furthermore, for a positive correlation as we have found, the overall effect will be negative only for sufficiently small values of the ratio $\varphi/[\Phi(1 - \Phi)]$.

This ratio $\varphi/[\Phi(1 - \Phi)]$ can be shown to have a U-shape, with a minimum at $4/\sqrt{2\pi}$ when $LC^* = 0$, and infinite value for LC^* tending to infinity. Therefore, with positive σ_{uv} , corresponding values μ and ν exist such that

$$\begin{aligned} e + \sigma_{uv} \frac{\varphi}{\Phi(1 - \Phi)} \leq 0 &\Leftrightarrow |LC^*| < \mu \\ &\Leftrightarrow |\Phi - .5| < \nu. \end{aligned}$$

The econometric results of table 3 give $e/\sigma_{uv} = 1.81$, for which $\nu = .34$. In other words, for all workers with a probability of being hired by a contractor between 16% and 84%, their wage

under a contractor is below the wage that they could expect under direct hiring, beyond the differential opportunity cost they may have under the two systems. Because this range covers the large majority of the sample, we can conclude that wages under contracting are consistently lower than under direct hiring.

This finding supports the hypothesis that contractors extract an equivalent amount of work from their employees at a lower direct labor cost than growers are able to achieve. On the one hand, they are compelled by competitive pressure to keep wages low. On the other, their ability to recruit workers with a lower opportunity wage and their greater immunity from unionization reduce the contractor's need to rely on positive wage incentives to increase the level of work effort.

Labor Policy, Contracting, and Expected Wages

Some of the factors determining the probability of contracting and the level of wages, discussed above, are subject to influence by state policies. State and federal governments, in fact, have a history of involvement in shaping employment contracts in agriculture, most notably through the administration of the Bracero Program during and after the Second World War. California is also one of the few states with legislation establishing collective bargaining rights for agricultural workers.

The implications of immigration and labor relations policies for the contract and wage structure of the farm labor market can be explored by comparing the expected wages of workers who differ in one or more of the characteristics affecting the probability of contracting and the wage for a given job and contract type. The results of the estimation are used to calculate expected wages from equation (16).

The results are presented in table 4. The worker characteristics that vary in the table are union status and legal status. The jobs examined are deciduous tree fruit harvesting, vegetable harvesting, and hoeing, with varying payment methods and locations. Among these, the highest wages are for vegetable harvesting on the coast and the lowest for hoeing in the Central Valley.

In each of the jobs examined in the table, expected wages are lowest for undocumented workers who are not unionized. It follows that

Table 4. Expected Hourly Wages for Workers with Selected Jobs and Characteristics

	Union		Nonunion	
	Legal	Illegal	Legal	Illegal
	----- (\$) -----			
Vegetable harvest, piece rate				
Central Valley	6.86	5.91	6.08	5.55
Coastal region	8.90	8.18	8.00	7.35
Deciduous harvest, piece rate				
Central Valley	7.22	6.40	6.29	5.64
Hoe, hourly rate				
Central Valley	5.43	4.65	4.87	4.45
Coastal region	7.19	6.65	6.51	6.04

Note: Calculated for a male worker with 10 years of farm work experience and working for a large employer (peak employment = 1).

the Immigration Reform and Control Act of 1986 should have the effect of increasing their wages for several reasons. First, the legal status of workers will increase their probability of working for a grower, which also will increase their expected wage. Second, assuming effective enforcement, a decline in the supply of undocumented workers will eliminate the contractors' advantage in drawing from this labor pool, thereby increasing relative per worker costs and reducing the relative efficiency of recruitment under contracting.

Unionization increases expected wages in each of the jobs examined, regardless of legal status. This is the combined result of a greater probability of direct hiring for unionized workers and the positive union wage effect among grower employees. These factors overcome the negative wage effect of union membership among contractor employees. Moreover, collective bargaining agreements usually restrict the use of contract labor even during seasonal peaks by obligating growers to hire through the union first. Thus, policies that promote farm labor unionization are expected to reduce contracting and increase wages in farm work.

Such policies are embodied in California's Agricultural Labor Relations Act (ALRA), which establishes the right to collective bargaining and provides an institutional framework for governing labor/management relations in agriculture. However, interpretation and enforcement of the ALRA are matters of political will. Without support from powerful employer organizations and labor to bring about acceptance of collective bargaining, it is unlikely that the share of union relative to contract labor will increase.

Conclusion

Three main findings support the theoretical model of labor contract choice presented in this paper. First, the effects of supervision and seasonality are confirmed by the finding that the probability of contracting is lower in jobs such as irrigating or equipment operator positions where work quality has a greater effect on output and where the length of employment is greater. Second, the higher probability of contract employment for undocumented workers, nonunion workers, and those with fewer years of farm work experience demonstrates the advantage of contractors in recruitment of workers whose opportunity costs of seasonal farm work are low. It also reveals their preference for workers who are least likely to pose a threat to management control of the labor process. Finally, the results show that, over a wide range, wages paid by contractors are lower than wages in direct hiring, net of differences in the distribution of jobs or workers between contract types.

The production process for most crops involves activities of short and long duration and requires varying levels of labor quality. Growers can, and the model predicts that they would be likely to, combine contract types over the growing season. Such a strategy would offer a further means of decreasing unity among workers, because differences in their wages, working conditions, and relationship to the grower would tend to isolate contracted from directly hired employees. Much more could be learned regarding contract choice by observing these patterns of labor use on farms.

The history of labor relations in agriculture has been marked by a sometimes intense struggle for unionization. This movement has challenged management's exclusive control of the labor process. The outcomes of the conflict are evident in the passage of the ALRA, improvements in working conditions, and the introduction of benefits and higher wages for agricultural workers. However, they are also evident in increasing mechanization, continuing political pressures from grower organizations to weaken the ALRA, and increasing use of the contracting system to reduce the threat of unionization. Neither the union movement nor the contracting system are likely to disappear from California agriculture. However, state policies that affect labor supply, such as immigration reform, and policies that determine the rights and protections afforded organized farm labor affect the relative efficiency of contracting. Hence, they

have the potential to reduce contracting's share of the farm labor market.

The Welfare Effects of Targeted Export Subsidies: A General Equilibrium Approach

Mary Bohman, Colin A. Carter, and Jeffrey H. Dorfman

A three-country model of export subsidies is developed with an exporter, an importer, and a neutral country which can act on either side of the market. When the neutral country is an exporter, the country offering a targeted export subsidy always suffers a welfare loss. However, when the neutral country is an importer, the possibility of a paradoxical result—that the subsidizing country can gain and the subsidized country can lose—is shown to exist, and the conditions under which this result occurs are derived. The model fails to provide justification (on national welfare grounds) for widespread use of targeted export subsidies such as the export enhancement program.

Key words: general equilibrium, international trade, policy, welfare.

This paper provides a comprehensive analysis of the terms-of-trade and welfare effects of targeted export subsidies in a static three-country model of international trade. Our objective is to show the precise conditions under which a targeted export subsidy improves the welfare of the subsidizing country and the welfare effects for the subsidized and other importing and exporting countries. Using a standard general equilibrium trade model (Dixit and Norman, Bhagwati) we demonstrate that, although it is theoretically possible for targeted export subsidies to be welfare enhancing, such a welfare gain is unlikely. Similar models have been applied to agriculture by Abbott, Paarlberg, and Sharples; and Dutton.

The theoretical results shed light on important policy issues because export subsidies have become an integral part of U.S. agricultural trade policy.¹ A general equilibrium approach is taken in order to determine both the terms-of-trade and income effects associated with a targeted export

subsidy program. The income effect will be empirically important for developing countries which receive agricultural export subsidies.

We build on the transfer literature where, for example, Bhagwati, Brecher, and Hatta show that transfer paradoxes (where the donor is made better off and the recipient is immiserized) occur only when “foreign distortions” are present.² We examine the welfare impacts for the subsidizing, subsidized, and other importing and exporting countries. Precise relationships among market shares, import demand elasticities, and export supply elasticities are derived to demonstrate the conditions necessary for a targeted export subsidy program to benefit or harm the different groups of countries.

The first section of this paper is a literature review. The second section develops the general equilibrium model employed to determine the welfare impacts of targeted export subsidies on all countries. Next, the effect of the subsidy on prices is investigated. The fourth section analyzes the welfare impacts on each country. Finally, a section discusses applications to empirical research, and then a summary section concludes the paper.

Dorfman is an assistant professor, Department of Agricultural Economics, University of Georgia. Authorship is jointly shared.

Giannini Foundation Paper No. 958.

Helpful comments and suggestions have been received from Giovanni Anania, Robert Feenstra, seminar participants at the University of Southern California, and three referees.

¹ For a good description of how U.S. agricultural export subsidy programs operate, see Seitzinger and Paarlberg (1989).

² The term “foreign distortion” is taken from an earlier Bhagwati piece. If a country is not using an optimal tariff, Bhagwati has referred to this as a “foreign distortion.” While we agree with one of the referees that this is misleading terminology (because such a tariff will lower world welfare), we continue to use it to be consistent with past literature.

Previous General Equilibrium Analyses

Global export subsidies are known to be welfare reducing in general, but special cases where they can be welfare increasing have been demonstrated by Brander and Spencer, Feenstra, and Itoh and Kiyono. Abbott, Paarlberg, and Sharples (APS) have examined targeted export subsidies and found that they too can be welfare improving. As with the transfer literature, these cases can be shown to result from either domestic or "foreign distortions" (e.g., failure to exploit the optimal tariff). In the case of imperfect competition, there also exist circumstances when export subsidies are part of a first-best policy.

Itoh and Kiyono use a model with three goods to show that subsidies on commodities which are marginal goods (defined as goods not exported at all or exported in small quantities under free trade but whose exports can be promoted considerably by export subsidies) can increase the welfare of the subsidizing country. This occurs because of effects on the production structure. A subsidy on marginal goods causes their production to increase and the supply of nonmarginal goods to decrease, thereby raising the price of the nonmarginal goods and increasing the exporter's terms-of-trade. The "distortion" in place is the failure to take advantage of the optimal tariff for the nonmarginal good.

Feenstra presents a case where export subsidies increase the welfare of the subsidizing country in a three-good, two-country model. He demonstrates that it is possible for the pattern of substitutability and complementarity across the three goods to allow for subsidies to increase welfare. The necessary condition is that the subsidized export be a stronger substitute of another export good, or stronger complement of an import good, in the subsidizing country than abroad. The distortion in this case is the failure to exploit market power in the second or third good. Feenstra points out that the gain in welfare results from nonzero terms-of-trade effects in the first good. However, the subsidizing country must also be large in the good where it gains from the change in relative prices. Failure to exploit this market power creates a "foreign distortion."

The imperfect competition literature presents a case for export subsidies as a first-best policy (Brander and Spencer). This occurs because, by allowing a firm to precommit to a higher level of output and therefore worsening the terms-of-trade, profits are shifted from the foreign to the domestic firm. These results are not robust to

changes in the nature of the strategic interdependence between the two firms.

APS develop a general equilibrium model for targeted export subsidies and show that the welfare effect for the subsidizing country has an ambiguous sign. Therefore, a welfare improvement is possible as a result of a targeted subsidy. They also briefly outline some of the market conditions necessary for this result to occur. APS use a three-country model with a subsidizing country, a targeted country, and the rest of the world. However, as Dutton points out, it is not clear from the APS paper why their paradoxical result arises. Dutton shows the APS result arises because they first constrain the export tax to the rest of the world to be zero and it then becomes theoretically possible for the best export tax to the targeted country to be negative. This is a second-best price discrimination strategy. In this case, the prohibition of export taxes results in too many exports to a country with less elastic demand. Therefore, a targeted export subsidy to a country with elastic demand shifts exports out of the less elastic market. This result hinges not only on the differences in elasticities across importing countries, but also on the exporting country having market power in trade.

The General Equilibrium Model

The model employed here consists of three countries (α , β , and γ) and two goods (X and Y). Both goods are produced and consumed by each country. The export subsidy is applied to good X , and it is assumed that free trade in Y exists. Country α is always an exporter who offers an export subsidy to country γ . Country γ is always an importer with no border policies and is the recipient of the export subsidy on good X from country α . Country β , the neutral country, is either an exporter or an importer and has no border policies. Country β can be thought of as the aggregate of all the other countries. If β is composed of a group of individual countries, assumed to have no border policies, then there is no loss of generality in treating all trade flows entering or leaving the group as if they originate from or go to a single country. When country β is referred to as an importer, this is equivalent to the rest of the world being a net importer. Referring to country β as an exporter is equivalent to saying that country α 's exports are less than country γ 's imports. In this case, the market will reassign the trading flows so that α ex-

ports only to γ as a result of the targeted export subsidy. Thinking of country β as a conglomeration in this sense allows the concept of a targeted export subsidy in the three-country model to carry over to the case when β is a net exporting region.

The objective of the analysis is to determine the effect of the targeted export subsidy on the welfare levels of the three countries. The following notation is used in the model: q^i is the relative price of good X in country i ; u^i , the welfare level of country i ; S , the per unit export subsidy on good X ; $e^i(q^i, u^i)$, the expenditure function of country i ; $r^i(q^i)$, the revenue function of country i ; and $x^i(q^i, u^i)$, the compensated net import demand function for good X by country i .

The price linkages among the different countries are crucial to the results obtained. There are several cases which can occur:

(i) Country β is an importer. Country α pays a global subsidy to both β and γ . The price linkage equation is

$$(1) \quad q^\alpha = q^\beta + S = q^\gamma + S.$$

(ii) Country β is an importer. Country α pays a subsidy for exports to country γ but sells to country β at the same price that prevails in α 's domestic economy. This is a targeted export subsidy case as in APS and Dutton, where, given market power by the exporter, the optimal policy would be to price discriminate. In this case the exporter fails to fully price discriminate; therefore, the subsidy can be seen as a second-best price discrimination strategy. The standard requirement of separation of markets is assumed. The price linkage equation is

$$(2) \quad q^\alpha = q^\beta = q^\gamma + S.$$

(iii) Country β is another exporter. If country α pays a subsidy on its exports to country γ , then country β also will sell to country γ at this lower price in order to remain competitive. The price linkage equation is

$$(3) \quad q^\alpha = q^\beta + S = q^\gamma + S.$$

Note that country β does not actually make a subsidy payment to country γ . Country β sells at the prevailing world price which is defined as the price paid by the importer and not the domestic price in the exporting country.

Cases (i), (ii), and (iii) are analyzed simultaneously by writing the price linkage equation as follows:

$$(4) \quad q^\alpha = q^\beta + I(\beta)S = q^\gamma + S.$$

$I(\beta)$ is an indicator function. $I(\beta) = 1$ when the neutral country's domestic price matches the domestic price in country γ . This occurs in cases (i) and (iii). $I(\beta) = 0$ when the neutral country's domestic price equals the domestic price in the subsidizing country, α . This takes place in case (ii).

The three cases differ in their assumptions about the price linkages between different countries and correspond to different trading patterns. Case (i), the general subsidy case, results in all trade taking place at one price. Country β receives a lower price due to the subsidy. In cases (ii) and (iii), only the selected importing country γ receives the subsidy and world trade occurs at two different prices. Each individual exporting or importing country will trade only at the most favorable price available. In case (ii), the subsidizing country will export to both the subsidized and nonsubsidized importing region. Exporting countries within the nonsubsidized region will only sell to nonsubsidized importing countries. The existence of two separate markets rules out the possibility of arbitrage. In case (iii), the net exporting region (β) sells to the net importing region (γ) at the subsidized price, which is also its domestic price since it has no border measures. The subsidizing exporter (α) sells only to the subsidized region.

The model employs duality theory in terms of compensated demand functions. The format follows Bhagwati, Brecher, and Hatta. As in their model, an overspending function is defined as follows:

$$(5) \quad c^i(q^i, u^i) \equiv e^i(q^i, u^i) - r^i(q^i), \quad i = \alpha, \beta, \gamma.$$

The value of this function gives the difference between total expenditures and revenues. For the country imposing the subsidy it represents minus the cost of the subsidy. The model can be written with four equations in four unknowns: q^α , u^α , u^β , and u^γ . The equations are as follows:

$$(6) \quad c^\alpha(q^\alpha, u^\alpha) + S[x^\gamma(q^\alpha - S, u^\gamma) + I(\beta)x^\beta(q^\alpha - I(\beta)S, u^\beta)] = 0,$$

$$(7) \quad c^\beta(q^\alpha - I(\beta)S, u^\beta) = 0,$$

$$(8) \quad c^\gamma(q^\alpha - S, u^\gamma) = 0,$$

$$(9) \quad x^\alpha(q^\alpha, u^\alpha) + x^\beta(q^\alpha - I(\beta)S, u^\beta) + x^\gamma(q^\alpha - S, u^\gamma) = 0.$$

Equations (6) through (8) are the budget constraints of the three countries. The subsidy cost

in equation (6) is based on the quantity sold by α at the subsidized rate. Equation (9) is the market-clearing equation for good X. By Walras' law, the market-clearing equation for good Y can be omitted. The price linkage equation (4) can be used to solve for q^β and q^γ once q^α is known.

Comparative Statics

The price and welfare effects of changes in S in cases (i), (ii), and (iii) are analyzed through total differentiation of the model. Throughout the paper, subscripts are used to indicate partial differentiation with respect to a variable. For example, $x_q^\alpha = \partial x^\alpha / \partial q$. We assume without loss of generality that $e_u^\alpha = e_u^\beta = e_u^\gamma = 1$ initially. In addition, $S = 0$ initially. Using Shepard's lemma we know that $c_q^i = x^i$, where x^i is the net import demand of country i . Finally, define $x_q \equiv x_q^\alpha + x_q^\beta + x_q^\gamma$. The differentiated system can be written as follows:

$$(10) \quad \begin{bmatrix} x^\alpha & 1 & 0 & 0 \\ x^\beta & 0 & 1 & 0 \\ x^\gamma & 0 & 0 & 1 \\ x_q & x_u^\alpha & x_u^\beta & x_u^\gamma \end{bmatrix} \begin{bmatrix} dq^\alpha \\ du^\alpha \\ du^\beta \\ du^\gamma \end{bmatrix} = \begin{bmatrix} -I(\beta)x^\beta - x^\gamma \\ I(\beta)x^\beta \\ x^\gamma \\ x_q^\gamma + I(\beta)x_q^\beta \end{bmatrix} dS.$$

Applying Cramer's rule to this system we obtain the following results, where $\Delta \equiv -(x_q - x^\alpha x_u^\alpha - x^\beta x_u^\beta - x^\gamma x_u^\gamma)$ and $\bar{x}_q^i = (x_q^i - x_u^i x^i)$ is the partial derivative of the Marshallian import demand function with respect to the relative price.

$$(11) \quad dq^\alpha/dS = -\{\bar{x}_q^\alpha + I(\beta)\bar{x}_q^\beta + x_u^\alpha(x^\gamma + I(\beta)x^\beta)\}/\Delta,$$

$$(12) \quad du^\alpha/dS = -\{x^\gamma \Delta + x^\alpha[\bar{x}_q^\gamma + I(\beta)\bar{x}_q^\beta + x_u^\alpha(x^\gamma + I(\beta)x^\beta)]\}/\Delta,$$

$$(13) \quad du^\beta/dS = \{x^\beta[I(\beta)\Delta - \bar{x}_q^\gamma - I(\beta)\bar{x}_q^\beta - x_u^\alpha(x^\gamma + I(\beta)x^\beta)]\}/\Delta,$$

$$(14) \quad du^\gamma/dS = \{x^\gamma[\Delta - \bar{x}_q^\gamma - I(\beta)\bar{x}_q^\beta - x_u^\alpha(x^\gamma + I(\beta)x^\beta)]\}/\Delta.$$

The denominator of each expression is the determinant of the (4×4) matrix in (10). This determinant, Δ , equals minus the slope of the

Marshallian general equilibrium global excess-demand schedule of good X. If we assume that the system is stable, then the Marshall-Lerner condition implies that $\Delta > 0$.

The Effect on Prices

In a partial equilibrium model, all results are caused by price (or terms-of-trade) effects. In contrast, the results of a general equilibrium model are also influenced by income effects. It is useful to analyze the price (terms-of-trade) effects separately. This clarifies the role that changes in prices and the terms-of-trade play in determining the welfare effects of targeted, and general, subsidies. At the same time, we have to remind ourselves that this is only part of the story.

The export subsidy's effect on prices can be investigated using equation (11). It is important not to interpret the domestic price as the world price because there is no case where all world trade takes place at q^α . In case (i), with a general subsidy and case (iii), with two exporters, all trade (although not all domestic sales) occurs at $q^\alpha - S$. In case (ii), with a targeted subsidy and one exporter, only a portion of trade takes place at q^α .

Case (ii)

In this case, β is an importer and α offers a targeted export subsidy to γ . The relative magnitude of the Marshallian income effects in countries α and γ determines whether dq^α/dS is positive. To see this, rewrite (11) as

$$(15) \quad dq^\alpha/dS = -\{x_q^\gamma - x^\gamma(x_u^\gamma - x_u^\alpha) + I(\beta)[x_q^\beta - x^\beta(x_u^\beta - x_u^\alpha)]\}/\Delta.$$

Recalling that in case (ii) $I(\beta) = 0$, a sufficient condition for dq^α/dS to be positive is that x_u^γ is greater than or equal to x_u^α . Note that because e_u^i is defined to equal 1 at the point in question, x_u^i equals the Marshallian income effect. Intuitively, $dq^\alpha/dS > 0$ requires that the increase in demand in the subsidized country exceeds the reduction in demand in the subsidizing country as a result of the changes in each country's domestic price.

Cases (i) and (iii)

In case (iii), the targeted export subsidy with two exporters, the sufficient condition for dq^α/dS

dS to be positive is that $x_u^\gamma > x_u^\alpha > x_u^\beta$. This can be seen in equation (15), remembering that x^β is negative for this case. In addition, when β is an exporter the value of dq^α/dS is always less than one, since (11) can be rewritten as

$$(16) \quad dq^\alpha/dS = 1 + x_q^\alpha/\Delta.$$

Continuing with case (iii), the effect of the subsidy on prices in α is more positive as α 's share of the export market declines. This results from the fact that as α becomes more of a price taker, its actions have less impact on the international market. Algebraically, this can be seen by expressing dq^α/dS in terms of elasticities and market shares. First, define ϵ^α as the price elasticity of demand for country α 's exports and ϵ^w as the price elasticity of the world excess demand function for the case where only country γ is an importer ($\epsilon^\alpha = x_q^\alpha(q/x^\alpha)$ and $\epsilon^w = \Delta(q/x^\gamma)$).³ Further, let κ be country α 's share of the export market; with β an exporter, this implies that $\kappa = x^\alpha/(x^\alpha + x^\beta)$. The necessary and sufficient condition for dq^α/dS to be positive is that $\epsilon^\alpha < \epsilon^w/\kappa$.⁴ As country β exports more, the right-hand side of the elasticity inequality becomes larger (as κ becomes smaller) and the condition is more easily satisfied (since both elasticities are defined to be positive).

In case (i), the global subsidy, a sufficient condition for dq^α/dS to be positive is that both x_u^α and x_u^β are greater than x_u^γ . The condition on the magnitudes of the income effects in α and β switches direction in case (iii) because β is an importer.

Welfare Effects

To analyze the welfare effects that are caused by the subsidy, equations (12) through (14) are rewritten below in terms of dq^α/dS and the quantities traded.

³ Note that a single price, q , can be used here since all expressions are being evaluated around an initial subsidy level of zero.

⁴ The proof of this result is as follows:

From eq. (16): $(dq^\alpha/dS) = 1 + x_q^\alpha/\Delta$.

Thus, we want

$$\begin{aligned} (dq^\alpha/dS) &= 1 + x_q^\alpha/\Delta > 0, \\ 1 + x_q^\alpha/\Delta &> 0, \\ x_q^\alpha/\Delta &> -1, \\ x_q^\alpha &> -\Delta, \\ x_q^\alpha &> -\Delta q, \\ x_q^\alpha(q/x^\alpha) &< -\Delta(q/x^\alpha), \\ \epsilon^\alpha &< -\Delta(q/x^\alpha), \\ \epsilon^\alpha &< -\Delta(q/x^\gamma)(x^\gamma/x^\alpha), \\ \epsilon^\alpha &< -\epsilon^w(x^\gamma/x^\alpha), \\ \epsilon^\alpha &< -\epsilon^w[(x^\alpha - x^\beta)/x^\alpha], \\ \epsilon^\alpha &< -\epsilon^w/(x^\alpha/[-x^\alpha - x^\beta]), \\ \epsilon^\alpha &< \epsilon^w/\kappa. \end{aligned}$$

$$(17) \quad du^\alpha/dS = -(x^\gamma + I(\beta)x^\beta) - x^\alpha(dq^\alpha/dS),$$

$$(18) \quad du^\beta/dS = x^\beta\{I(\beta) - (dq^\alpha/dS)\} \\ = -x^\beta(dq^\beta/dS),$$

$$(19) \quad du^\gamma/dS = x^\gamma(1 - dq^\alpha/dS) \\ = -x^\gamma(dq^\gamma/dS).$$

These equations highlight the role of the change in the terms-of-trade. The welfare result in equation (17) is composed of an income effect and a terms-of-trade effect. In equations (18) and (19) the welfare effect depends entirely on the terms-of-trade effect because these countries incur no subsidy costs.

Effects on the Subsidizing Country

The welfare of the subsidizing country always falls when the neutral country is an exporter. However, the welfare effect is ambiguous with a targeted subsidy when the neutral country is an importer.

Cases i and iii. In cases (i), a global subsidy, and (iii), where the neutral country is an exporter, $-(x^\gamma + I(\beta)x^\beta)$ equals x^α . For these two cases, the welfare loss can be seen by simplifying (17) when $I(\beta) = 1$ to

$$(20) \quad du^\alpha/dS = x^\alpha(1 - dq^\alpha/dS).$$

Therefore, utilizing equation (16) which shows that dq^α/dS is less than one when $I(\beta) = 1$, du^α/dS is unambiguously negative with a targeted subsidy when country β is an exporter and for a global subsidy. Thus, we conclude that for both cases (i) and (iii), $du^\alpha/dS < 0$. As in the case of the two-country model of standard trade theory, offering a general subsidy is always welfare decreasing in the three-country case both when offered to all countries and when a subsidy is targeted to one importing country in the presence of another exporter or net exporting group.

Case ii. In case (ii), with the neutral country an importer, the possibility arises of a paradox where the subsidy causes welfare in the subsidizing country to rise. Using equation (17) the necessary and sufficient condition for du^α/dS to be positive when the third country is an importer is that $dq^\alpha/dS > \lambda$ where λ is γ 's share of world imports, $\lambda = x^\gamma/(x^\beta + x^\gamma)$. Thus, as the share of α 's exports to γ increases (and, conse-

quently, the share to country β decreases), du^α/dS tends to be negative because λ increases. This occurs because country α is exploiting β through the targeted subsidy to γ . The larger β 's share of country α 's exports, the more opportunity to earn extra revenue by the price discriminating effects of a targeted subsidy, and the more likely that country α 's subsidy will be welfare improving.

The ambiguous sign of du^α/dS for case (ii) can be explained by the fact that the exporter is failing to take advantage of its market power in good X . The use of the subsidy captures some of the benefits of α 's power in β 's and γ 's markets but still leaves country α with less than the maximum attainable welfare. In a similar manner to the case of transfers, the paradox arises from the presence of a "distortion" (the failure to exercise market power). See Dutton for further clarification of this result.

Effects on the Neutral Country

The expression in (18) for country β 's welfare change can be interpreted solely as a terms-of-trade effect. The welfare of the neutral country falls when the change in its terms-of-trade is unfavorable.

Cases i and iii. Country α 's decision to offer a subsidy reduces not only its own welfare but also that of all other exporters. The effect of the subsidy depends on whether the neutral country is an exporter or an importer. Remembering that $I(\beta) = 1$ for both cases (i) and (iii), in case (i), with a global subsidy, β 's welfare improves. In case (iii), with a targeted subsidy when β is an exporter, $dq^\alpha/dS < 1$ by equation (16), and β must suffer a welfare loss as a result of the subsidy offered by α . The change in sign of the welfare impact on country β is caused by the switch in sign of x^β , the net import demand of country β , between the global subsidy, case (i), where β is an importer and case (iii) where β is an exporter. Country α 's decision to offer a subsidy reduces not only its own welfare, but also that of all other exporters.

Case ii. In case (ii) country β is an importer not receiving α 's targeted export subsidy. By equation (18) du^β/dS equals minus net imports times the change in the price of its imports due to the targeted subsidy. In this case the price in

β is equal to the price in α , therefore country β is made worse off if and only if $dq^\alpha/dS > 0$. If country β is made better off, country α must suffer a loss in welfare. The exact necessary and sufficient condition for $dq^\alpha/dS < 0$ can now be expressed in terms of elasticities to help in a later comparison of the welfare changes in β and γ . Thus, for case (ii), $du^\beta/dS > 0$ if and only if

$$(21) \quad q(x_u^\alpha - x_u^\gamma) > \epsilon^\gamma.$$

In (21), ϵ^γ is the (positively defined) elasticity of demand for good X in country γ , $\epsilon^\gamma = -x_q^\gamma(q/x^\gamma)$. This specification agrees with the sufficient condition for dq^α/dS concerning the direction of the price change ($x_u^\alpha > x_u^\gamma$) but extends it to the necessary and sufficient condition. Thus, as an importer, country β suffers a drop in utility when the domestic price in country α rises.

When it is an importer, β is the country most affected by the difference between a targeted or a general subsidy from α . Country β would benefit from a global subsidy which would lower the price of its imported good but will normally lose if α only offers a targeted export subsidy to γ .

Effects on the Targeted Country

In general country γ 's welfare increases as a result of the subsidy. Only in case (ii) when β is an importer is the paradoxical result that γ is immiserized by the targeted subsidy from α possible. As in the case of country β , the welfare change in country γ is a straightforward terms-of-trade effect. Irrespective of whether β is an importer or an exporter du^γ/dS is positive if and only if dq^γ/dS is negative, representing a terms-of-trade gain.

Cases i and iii. In case (iii) when country β is an exporter, country γ 's welfare improves with a subsidy. Equation (16) shows that $[1 - (\epsilon q^\alpha/dS)]$ must be positive for case (iii) which ensures that γ is made better off. As in the case of subsidies in the classical two-country model of trade, in the presence of another exporter, the importing country cannot be immiserized by the subsidy. The result also holds for case (i), the global subsidy.

Case ii. In this case, when the neutral country is an importer, the possibility of a paradoxical

result exists. If dq^α/dS is greater than unity, then country γ is immiserized. Returning to the earlier elasticity representations, the necessary and sufficient condition for this to occur when β is an importer is⁵

$$(22) \quad q(x_u^\gamma - x_u^\alpha) > (\epsilon^w/\lambda) - \epsilon^\gamma.$$

The price elasticity of the Marshallian world excess demand (defined to be positive) is given by $\epsilon^w = \Delta[q/(x^\beta + x^\gamma)]$ to reflect the fact that country β is an importer, $\epsilon^\gamma = -x_q^\gamma(q/x^\gamma)$ as before, and λ is, as above, the share of total world imports imported by the targeted country, $\lambda = x^\gamma/(x^\gamma + x^\beta)$. The paradoxical result of γ being made worse off by a subsidy can occur if and only if there exists a large difference in the income effects of countries α and γ .

The condition in (22) can be rewritten as follows to offer additional intuition.

$$(23) \quad x_q^\beta + x_q^\gamma + x^\beta(x_u^\alpha - x_u^\beta) > 0.$$

From (23) it can be seen that a large income effect in α will make the paradox more likely. The result is similar to the Metzler paradox. Recall that the x functions are net import demand functions. The subsidy initially results in the import price falling in γ and a rising in β . If the rise in the import price has a small impact on β 's net import demand (due to small price and income effects), then α 's exports to β will not fall much. This condition, combined with the increased (subsidized) exports to γ , causes domestic supply in α to fall and increases the domestic price. If the domestic price increases enough, even the subsidized price will be above the pre-subsidy price level; this scenario results in the immiserization of country γ .

The conditions necessary for the paradoxical result that γ is made worse off precludes the subsidy improving β 's welfare. A comparison of (21) and (22) shows that in case (ii) when country β is an importer, the condition for β to be made better off from being (price) discriminated against (i.e., not receiving a subsidy) can be met if and only if the subsidy is welfare increasing for country γ . This result follows from the fact that α can only gain utility if $dq^\alpha/dS > \lambda$, which is positive by definition. Equation (18) shows that if $dq^\alpha/dS > 0$, then du^β/dS is negative when β is an importer. It can also be shown, using (17) and (19), that if α loses utility from the subsidy, then γ must gain utility. This oc-

curs because when α loses utility $dq^\alpha/dS < \lambda < 1$, and from (19) this implies that γ must gain utility. Therefore, in the unlikely, but possible, event that γ suffers a loss in utility by receiving a subsidy, α will gain utility and β will lose utility. The above comparison of du^α/dS to λ allows a simple proof by contradiction of this last result.

Summary of Comparative Static Results

The price and welfare effects of the three cases above are summarized in table 1. Case (i) represents a global subsidy to both the neutral and subsidized country; case (ii) represents a targeted subsidy to the subsidized country, with the neutral country as an importer; case (iii) represents a targeted subsidy to the subsidized country with the neutral country as an exporter. The price effects are summarized in the top panel of table 1 and the welfare effects in the bottom panel.

Implications for Policy and Empirical Research

The results from the general equilibrium model can be used to evaluate recent empirical research on export subsidies for U.S. agricultural products. Empirical applications have generally been partial equilibrium in nature and most have focused on the U.S. Export Enhancement Program for wheat. In general, welfare calculations are not made. This section discusses the conclusions from the theoretical model that apply to policy issues and empirical research and evaluates some recent models.

Changes in the terms-of-trade can be used to infer welfare results for the different groups of countries. Equations (17)–(19) show that the changes in welfare hinge on changes in the terms-of-trade for each country. The empirical models often calculate changes in the terms-of-trade but report only changes in total revenue and not price changes. Given the importance of the terms-of-trade to welfare changes, future research should report this result.

The theoretical results also show the importance of the share of the market which is subsidized. The λ and κ parameters representing market share appear in the welfare conditions summarized in table 1. Recall that λ is γ 's share of world imports when β is an importer, and κ is α 's share of the export market with β an ex-

⁵ Because $S = 0$, $q^\alpha = q^\beta = q^\gamma = q$. We need only q^i for differentiation, e.g., dq^α/dS .

Table 1. Summary of Welfare Results

Country	Case <i>i</i>	Case <i>ii</i>	Case <i>iii</i>
		Price Effects $dq^a/dS > 0$ if	
Exporter(α)	$x_u^\gamma > x_u^\beta > x_u^\alpha$	$x_u^\gamma > x_u^\epsilon$	$\epsilon^\alpha < \epsilon^w/\kappa$
		Welfare Effects $du^i/dS > 0$ if	
Exporter (α)	Never	$dq^a/dS > \lambda$	Never
Neutral (β)	Always	$*q(x_u^\alpha - x_u^\gamma) > \epsilon^\gamma$	Never
Subsidized (γ)	Always	$*q(x_u^\gamma - x_u^\alpha) > \frac{\epsilon^w}{\lambda} - \epsilon^\gamma$	Always

Notes: Case *i*: global subsidy to both the neutral (β) and subsidized (γ) countries; Case *ii*: targeted subsidy to γ , with β an importer; Case *iii*: targeted subsidy to γ , with β an exporter. x_u^i is Marshallian income effect; ϵ^α is price elasticity of demand for country α 's exports; ϵ^w is price elasticity of demand of the world excess demand function; κ is exporter's (α 's) share of the export market for case *iii*; λ is subsidized country's (γ 's) share of imports for case *ii*; and ϵ^γ is absolute value of price elasticity of demand in subsidized country (γ). Asterisk indicates it cannot happen simultaneously.

porter. In the case of the EEP, the percentage of U.S. exports receiving subsidies has grown over time to the point where in 1988, EEP sales approached 29 million metric tons (mmt), which was 70% of U.S. wheat sales. The results of any model designed to analyze the program are sensitive to the time period chosen. Therefore, the possibility of an increase in U.S. welfare from the EEP has fallen over time and the results in Seitzinger and Paarlberg (1990), for example, are probably no longer valid.

Results from the theoretical model may not be directly comparable to those from various empirical models because of different underlying assumptions. The theoretical model presented in this paper assumes perfect competition and no other policy intervention besides the export subsidy. The price linkage equations reflect these assumptions and result in specific trade flows. The different trade flows that have occurred with EEP could reflect the fact that the world wheat market is not perfectly competitive. Also, the theoretical model does not incorporate policies other than export subsidies. Results from empirical models which contradict the theoretical welfare effects could occur because of the way that stocks, support prices and other policies are modeled. General welfare effects cannot be derived if other distortions exist.

APS used a spatial equilibrium model to calculate optimal targeted export subsidies. They found that small subsidies resulted in a small welfare gain relative to free trade for the subsidizing country. This is consistent with the theoretical result that welfare-improving targeted subsidies occur under constrained price discrimination in our case *ii*.

Seitzinger and Paarlberg (1990) analyze quarterly EEP sales using a game theory approach and a spatial equilibrium model. They do not calculate overall welfare effects. However, they do calculate changes in the terms-of-trade for the United States and changes in total revenue for other exporters. They estimate that the U.S. border price is higher with EEP for October to December 1985. This result could only be supported by our theoretical results if the share of EEP sales in total U.S. exports was small.

Haley used a spatial equilibrium model to analyze the effect of the EEP in 1986/87 but did not calculate welfare changes. In Haley's model, subsidies exist with shared markets between the subsidizing exporter and nonsubsidizing exporters. He found that subsidies lowered the prices received by competing exporters which agrees with our theoretical result. Similarly, to Seitzinger and Paarlberg (1990), he finds the U.S. export price rises, which is possible but not probable, given our theoretical results.

Conclusions

This paper analyzes the welfare impacts of targeted export subsidies using a three-country, two-good model. The commercial policies of each country and its position in the world market (exporter or importer) are exogenous to the model. One country subsidizes its exports, and there is a recipient and a neutral country. The results show that the neutral country's market position (importer or exporter) and its market share influence the welfare results for all countries. The effect of the subsidy on the domestic price in

the country offering the subsidy, the slopes of the various excess demand functions, and the magnitudes of the income effects are all important to the welfare results.

When the neutral country is an exporter, the subsidizing country must suffer a loss of welfare as a result of offering a targeted subsidy. Further, as an exporting country, the neutral country must suffer a loss in welfare while the subsidized country benefits from the subsidy. With two importing countries, a targeted export subsidy reduces the welfare of the subsidizer unless targeted toward a country with a small market share and/or a higher than normal income elasticity of demand.

In general, the qualitative effects of a targeted export subsidy differ little from a general subsidy. A targeted subsidy imposes less of a welfare cost because it is offered to only part of the market. However, if an exporter is in a position such that it can gain through offering a targeted subsidy, then it should take full advantage of its market power and price discriminate using export taxes if it chooses to maximize its welfare by abandoning free trade to a beggar-thy-neighbor policy (see Dutton).

Export subsidies have been shown to be similar to (international aid) transfers. As demonstrated in Bhagwati, Brecher, and Hatta, a three-country model is essential to finding the paradoxical results where the country being granted aid in the form of a transfer or subsidy is actually immiserized by it. The neutral third country is crucial because this paper has shown that such a paradox can exist only when the third country is an importer and is not receiving the subsidy. Similarly, in the Bhagwati, Brecher, and Hatta case, a transfer can only immiserize the recipient country when the neutral country is an exporter. The case of targeted export subsidies also mirrors the case of transfers in that only one of the two importers benefits from the subsidy while the other loses welfare. Thus, when the subsidized country is immiserized, the neutral country benefits. In a final parallel to the transfer case, it is possible for the neutral country to lose welfare while the subsidized and subsidizing country both gain welfare. This case is an exact analogy to what Bhagwati, Brecher, and Hatta refer to as the "invisible shakedown."

Targeted export subsidies for agricultural exports have been used extensively by the United States since 1985 in order to regain market share. However, the model presented in this paper fails to provide justification (on national welfare grounds) for the widespread use of targeted ex-

port subsidies. Instead, the results of this paper suggest that a targeted export subsidy program is likely to be suboptimal trade policy. In agricultural trade, the neutral countries tend to be net exporters, and thus the United States stands to lose welfare as a result of targeted export subsidies.

The result that the welfare of the subsidizing country falls as the share of the subsidized market increases argues against expansion of current programs. The growth of export subsidy programs over the past few years has been at the expense of national welfare. One caveat is the use of subsidies as part of strategic trade policy to induce other exporters to change their trade policies. This dynamic, multiperiod strategy is not incorporated into the static model used in this paper.

This paper also demonstrates why exporting neutral countries have objected so strongly to subsidy programs. The EEP was originally designed to punish the EC for their export subsidies (as explicitly modeled by Seitzinger and Paarlberg). The U.S. Department of Agriculture claimed that other exporters would not be damaged. However, Canada and Australia immediately recognized that U.S. export subsidies adversely affected their terms of trade. Their complaints are supported by the results of this model.

The Costs of Indonesian Sugar Policy: A Policy Analysis Matrix Approach

Gerald C. Nelson and Martin Panggabean

Indonesian sugar policy is a complex web of contradictory policies, including mandatory production, price supports, and fertilizer and credit subsidies. The policy analysis matrix (PAM) was developed by Monke and Pearson to provide a more complete perspective on social profitability and the divergence between private and social costs than other commonly used social cost-benefit measures. The PAM is used to analyze the effects of Indonesian sugar policy on sugar production in irrigated and dryland areas on Java, the main sugar-producing region in Indonesia, and to identify the distribution of resource transfers.

Key words: food policy, Indonesia, policy analysis matrix, social cost-benefit analysis, sugar.

Policy analysts who use the tools of applied welfare economics face the challenge of presenting their results to policy makers who have little time to spare and varying degrees of analytical sophistication and training in welfare economics. Hence, a central part of theoretical efforts in this field has been the search for theoretically correct and easily understandable summary measures of policy impacts on social welfare. Two types of summary measures have been developed. One strand of analysis focuses on the private and social costs of public sector investment. Popular measures in this area include the net present value (NPV), and the economic internal rate of the return (EIRR). (See Gittinger for a widely used reference to these measures.) The second strand of analysis focuses on the static effects of price-distorting policies. Popular measures of the effects of price policies include the effective protection coefficient (EPC) (e.g., Corden, Balassa and Schydowsky) and the domestic resource cost of foreign exchange (DRC). (See Krueger, and Bruno 1967 for the original statement, a series of ar-

ticles in the *Journal of Political Economy* in the early 1970s, e.g., Bruno 1972, and Pearson, Akrasanee, and Nelson for a restatement and use in an agricultural context.)

Each of these measures has advantages and disadvantages, depending upon the type of analysis conducted. However, the danger with any summary measure is that it may summarize too much, and important results of the analysis go unnoticed. A new technique, the policy analysis matrix (PAM) addresses this problem (Monke and Pearson). The PAM was developed by Pearson et al. and grew out of a history of policy analysis using the DRC approach (e.g., Pearson and Cownie, Pearson et al., Falcon et al.). The basis of the PAM is a set of profit and loss identities that are familiar to any businessman. One strength of the PAM is that it allows varying levels of disaggregation. Another is that it makes the analysis of policy-induced transfers straightforward. Finally, the PAM makes it possible to identify the net effect of a set of complex and contradictory policies and to sort out the individual effects of those policies. As the intellectual successor to the DRC and NPV calculations, the PAM also suffers from some of their weaknesses. Principal among these is the assumption of fixed input-output coefficients (although Monke and Pearson argue that it is possible to introduce supply response parameters into the PAM). Production is characterized by a series of techniques, each of which has fixed

input-output coefficients and represents some share of the total production.

Analysis of the Indonesian sugar sector is an ideal candidate for use of the PAM. While Indonesian policy makers have a deserved reputation for managing their economy well, the Indonesian sugar sector is a conspicuous exception to that record of good economic policy. This paper uses the PAM to examine the social cost of achieving (at least through the late 1980s) the policy goal of self-sufficiency in sugar production. Four sets of policy instruments contribute to that social cost.

In the next section, a brief history of Indonesian sugar cultivation and description of current policies is presented. The third section provides a summary of the policy analysis matrix approach and discussion of data and modeling assumptions. The fourth section presents results and the final section some concluding remarks.

A Brief History of Sugar Cultivation, Trade, and Policies in Indonesia

Sugar is a processed form of sugarcane (*Saccharum officinarum*), a plant that originated in New Guinea.¹ The dispersion of sugarcane from New Guinea followed three routes, one of which passed through Indonesia. It seems likely that sugarcane has been grown in Indonesia at least since 1 A.D. (Husz, Blackburn).

Before the seventeenth century, sugar exports were small compared with spice exports, the primary reason traders came to Indonesia. The importance of sugar in Indonesia changed in 1830 when the Dutch colonists introduced the *Cultuur Stelsel* (translated freely as the Cultivation System) which was so successful that it became the mainstay of the Netherlands' prosperity (see for example, Sievers for a description of the Cultivation System). The central element of the Cultivation System was that farmers were forced to provide land and labor to produce export crops. Production decisions were made by the colonialists and their employees. In 1870, the Dutch parliament passed the Sugar Act, which removed sugar from the Cultivation System, and the Agrarian Act, which institutionalized the practice of long-term leases of land for cultivation of crops for export. The "Glebagan" sys-

tem arose from these changes. Under this system, farmers near a sugar mill were required to lease their land to the mill for one year in three.

By 1930, Indonesia was the world's second biggest sugar producer and exporter after Cuba. The 1930 Depression began the decline in the Indonesian sugar industry as the bottom dropped out of world demand. Efforts to rejuvenate production after the Depression were halted by World War II. The Japanese occupiers destroyed many sugar mills, and the Indonesian war of independence (1945-49) also saw more destruction of sugar mills.

Although the Glebagan system remained in effect after the war, the need to increase food production, especially rice, after independence made it difficult for sugar mills to continue the prewar practice of managing cane production on land leased from smallholders (Mubyarto 1969). To assure an adequate supply of cane, mills began to rely on independently grown smallholders' cane. For the first time, smallholders established an important role as cane suppliers.

Beginning in 1952, a series of legislative reforms were passed in an attempt to remove some of the inequities associated with the long-term lease provisions of the colonial Agrarian Law (Soetrisno, Mubyarto 1969). These culminated in the TRI system, described below, in 1975.

The first half of the 1970s saw a sizable recovery in cane production with average annual sugar output of 840,000 metric tons, almost 200,000 metric tons larger than production for most of the 1960s (table 1). This growth was due to two factors (Mubyarto 1977), an increase in yields and area expansion induced by movements in sugar and rice prices and an increase in areas designated for sugar production. But an important source of these improvements lies in the change of government and the improved economic environment after 1965, which led to improvement in roads, other infrastructure, administration, and management efficiency.

The compulsory leasing of farmland to mills, a crucial element of the Glebagan system, was eliminated in February 1975, when the government issued Presidential Instruction No. 9. This new law was designed to encourage farmers, rather than mills, to manage the sugar production on their land. The new program, called the Smallholder Cane Intensification Program and known by its Indonesian acronym, TRI, involved a package of credit and inputs. Instead of leasing land to the mills, farmers were forced to cultivate cane periodically to ensure an adequate supply of cane to the mills.

¹In Indonesia, the word "sugar" is used to refer to various kinds of sweeteners, some of which came from plants other than sugarcane. In this paper, however, sugar means a refined, white sugar processed from sugarcane.

Table 1. Area, Production, and Yield of Sugar on Java (Average of Selected Years)

Year	Area (000 ha)	Production (000 ton)	Sugar Yield (mt/ha)	(off-Java area) (000 ha)
1954-59	63	697	11.1	NA
1960-69	81	644	8.0	NA
1970-74	92	859	9.3	NA
1975-79	138	1,118	8.1	NA
1980-84	244	1,485	6.1	24.4
1985-87	310	1,959	6.3	66.4

Source: Mubyarto (1969, 1977) for years before 1970. After 1970 from Balai (later Pusat) Penyelidikan Perusahaan Perkebunan Gula, *Laporan Tahunan*, various years. Includes only cane grown for granular sugar production.

The main features of the TRI system, which remains in place today, are as follows: (a) Farmers whose land is in a designated cane production area are required to cultivate cane, but in not more than two consecutive seasons. After that period, they are allowed to cultivate other crops until their land is again designated for cane production, typically after two years.² (b) Farmers are provided with credit at subsidized interest rates (12%) by Bank Rakyat Indonesia (BRI). This credit is given in four tranches according to the stages of cultivation and is for both inputs and living allowances. (c) Farmers are required to use seeds, pesticides, and fertilizers distributed by the mills. (d) Farmers are required to submit all of their cane production to the mills, and the mills are required to accept and process it. (e) Payment is determined by the rate of extraction of sugar from the cane (for the typical extraction rate of 8%, farmers receive 55% of sugar output). All of the farmers' share is bought by the government at prices announced at the beginning of the planting season. Farmers receive payment in cash net of loan repayment.

After the TRI program was implemented, cane cultivation expanded to new areas not previously utilized for cane production. Cane grown on irrigated land grew at an average annual rate of 8.52% during the 1980-86 period, while dryland cane area (including land off-Java) grew at an annual average of 12.30%. Since 1984, dryland cane area has been larger than irrigated cane area (*Tim Survai* [Anonymous]; see also Brown for a more extended description of efforts to expand sugar production off-Java).

²As a grass, new cane can sprout from roots left in the ground after the first crop is cut. A typical rotation might be to plant cane, harvest the first crop 16 months after planting, allow new cane to grow from the old crop roots and harvest the second, "ratoon" crop 12 months after the first harvest. Sugar yields typically decline markedly after the second crop.

Sugar Marketing and Price Control

The history of sugar marketing in Indonesia is checkered by failed experiments with different forms of state/private management. The first collective sugar-marketing body, NIVAS (*Nederlandsch Indische Vereniging voor de Afzet van Suiker*), was established in 1931 by all of the sugar mills to secure overseas markets during the world depression (Mubyarto 1969). NIVAS' other functions were securing the collection of duties imposed on sugar and control of domestic consumption to maintain export levels (Soetrisno).

When the sugar mills were nationalized in 1957, NIVAS stopped functioning. As with production regulations, government policies with respect to processing underwent many changes during the 1960s and early 1970s. By the early 1970s, the government agencies in charge of processing and marketing were (Soetrisno): (a) Ministry of Agriculture, whose responsibility was to manage the state-owned sugar mills' production; (b) Bank Bumi Daya, which acted as the mills' creditor and sugar stockholder and was responsible for financing; and (c) BULOG (the National Logistics Agency), which was responsible for procurement, distribution, and marketing of all sugar.

In 1980, the government issued a decree stating that beginning in 1981 all domestic sugar production, regardless of ownership or method of production, would be bought by BULOG except 1% (later increased to 2%) of TRI farmers' production for use in their own consumption.

Since independence, sugar has been one of nine basic commodities whose prices are controlled. Sugar price control is implemented at the mill gate. Since 1969, the Provenue price, which is effectively the net payment received by mills, has been fixed annually by the government, and the ex-mill price is determined by

adding various fees, taxes, and miscellaneous charges. The Provenue price is determined in consultations among the Ministries of Agriculture, Trade, Finance, and BULOG and is based on the mills' cost of production plus a profit margin and an allowance for inflation. Under normal circumstances, the Provenue price for a particular year is announced at the start of the harvest season of that year's cane, which is also the beginning of the next year's cane planting season.

In recent years the world price for sugar has been much lower and more variable than the domestic price (table 2). In the 1980s, the nominal protection coefficient (NPC) has generally been between 40 and 80, with the fluctuations primarily as a result of changes in the world price.

Present policies on marketing and price control are implemented by BULOG. BULOG is the sole buyer of all domestically produced sugar, except for the 2% of farmers' output retained for own consumption. BULOG is also the sole importer of sugar. In addition, BULOG heavily influences domestic distribution of sugar (Sapuan et al.) through its role in appointing regional wholesalers who are permitted to obtain supplies from its regional warehouses.

In summary, four policy instruments affect the sugar sector directly. As in many LDCs, both producer and consumer prices of sugar are generally well above world prices.³ Second, in spite of high prices, the government has to compel some farmers on Java to plant sugarcane. Java

has unique physical characteristics that make its land suitable not only for growing sugar cane but also for producing rice and other food crops such as corn and soybeans. The fact that rice is an alternative crop presents policy makers with a special dilemma since rice self-sufficiency is the single most important agricultural policy goal. Third, fertilizers and other chemical inputs are subsidized. Finally, most cane producers receive a substantial credit subsidy.

The Policy Analysis Matrix (PAM)

The PAM consists of two accounting identities (table 3). The first identity states that profit is equal to revenue minus costs, measured in either private or social terms; the second identity measures the differences between observed values and the levels that would exist if the divergences between private and social prices (caused by distorting policies or market failures) were removed.

On the first line of the matrix is the calculation of private profitability (D), defined as revenue (A) minus total costs ($B + C$), where all inputs and outputs are valued at market prices. A positive private profit indicates the market competitiveness of a commodity system under investigation, given input and output prices, technologies, and government policies.

The second line of the matrix measures social profitability, which is social revenue less social costs. To arrive at the second row of the matrix, social prices (which reflect the underlying scarcity and thus the optimal allocation of resources) are used to value inputs and outputs. A positive social profit indicates that the system uses scarce resources efficiently and contributes to national income (i.e., the commodity has a static comparative advantage).

The second accounting identity, found in the third row of the table, is the difference between the first and second rows. If market-failure correction policies by the government do not exist (or are negligible), any differences between the first row and the second row must be caused by distorting policies. The third row also reflects transfers between producers on one side and government treasury and consumers on the other side. Under certain restrictive assumptions, transfers to producers are identical to producer surplus and transfers to consumers are identical to consumer surplus.⁴

³Unlike sugar, producers receive less than the world market price for molasses. First claim on molasses is by those mills with their own alcohol factories. The second is for use in domestic industry. The remainder is exported through a state-owned marketing board.

Table 2. Price Comparison between Adjusted CIF Price and Wholesale Price for Sugar (1981–86)

Year	Adjusted CIF Price (000 RP/mt)	Wholesale Price (000 Rp/mt)	NPC ^a
1981	349	502	44
1982	207	523	53
1983	296	532	80
1984	219	565	58
1985	195	600	208
1986	347	611	76

Source: Rosegrant et al., p. 4.34, 1987.

Note: The adjusted CIF is the actual CIF price at the port adjusted for internal marketing costs necessary to transport the sugar to the wholesale market.

^aNPC is the nominal protection coefficient.

⁴The assumptions necessary for this to be true include supply and demand elasticities equal to zero and no changes in input prices.

Table 3. An Outline of the Policy Analysis Matrix

	Revenues	Costs		Profits
		Tradable Inputs	Domestic Factors

^d Input Transfers, $J = (B - F)$.

^e Factor Transfers, $K = (C - G)$.

^f Net Policy Transfers, $L = (D - H) = (I - J - K)$.

Data and Modeling Assumptions

The sugar production, processing, and marketing system can be represented by three separate activities. The first activity, farm production, consists of cane production and transportation to the mills. Processing is the second activity, with cane as the input and sugar as the output. Transportation of sugar to the wholesale market, at which level the domestic sugar price can be compared with the CIF import price, is the third activity.

The possibility of multiple harvests from a single planting complicates the analysis. Cane usually needs sixteen months from land preparation to harvest. Once cane is harvested, however, roots intentionally left in the ground grow again. This second or "ratoon" crop needs only twelve months to mature. This process can go on for several generations, producing less yield with each subsequent generation. On irrigated area, cane is rarely grown for more than one ratoon, while on dryland area two ratoons are common. Each generation utilizes different amounts of inputs and produces different amounts of output. The farm-level activity thus is modeled as five separate representative farms: S I, S II, T I, T II, and T III, where S I denotes first generation cane planted on irrigated land, T I denotes first generation cane planted on dry-land area, and so on.

Because the Indonesian economy is relatively undistorted, determination of social prices was straightforward. To determine the shadow exchange rate, it is necessary to compensate for overvaluation from two sources, differential inflation and the structure of protection. A devaluation in 1986 eliminated the effects of differential inflation on the exchange rate, and the shadow exchange rate reflects only the distor-

tion associated with the structure of protection, approximately 8% (see Panggabean, p. 28, for details). The Indonesian rupiah is freely convertible, and capital mobility is essentially unlimited. Therefore, the market interest rate for loans to similar agricultural activities was used as the social interest rate (20%). Pearson et al. report that agricultural labor markets function in a relatively competitive manner. Therefore, the market and social wage rate are assumed identical. The private (social) opportunity cost of land is calculated as the difference between the private (social) revenue and variable costs of the crops replaced by cane. The S I and T I cane crops are assumed to take sixteen months, while the S II, T II, and T III crops require only twelve months. The crop combinations used to calculate the opportunity cost of land are (see Monke and Pearson, pp. 210-11 for an example of this type of calculation):

S I—2 irrigated rice, 1 maize, 1 soybean
(first crop, irrigated cane)

S II—2 irrigated rice, 1 maize
(second crop, irrigated cane)

T I—2 dryland rice, 1 soybean
(first crop, dryland cane)

T II/III—2 dryland rice each
(second and third crop, dryland cane).

Data for 1987 were used because they are reasonably representative of expected long-run levels of domestic and world prices of inputs and outputs. Finally, because off-Java area is relatively small and data on production techniques and costs off-Java are not available, the analysis is limited to Java cane production. A technical appendix with further details is available from the authors.

Results and Discussion

The basic results from the farm production activity's budget can be divided into two main categories: cane produced by farmers joining the TRI program (table 4) (75% of the total cane area in Java), and other cane including cane grown by the mills (details not reported here). The only difference between the two is the subsidized interest rate TRI farmers receive.

The results indicate that in 1986/1987 both dryland and irrigated cane cultivation were socially unprofitable.⁵ The principal cause of that result is the opportunity cost of the land. For most of the cultivation techniques, the opportunity cost of land was equivalent to a large share of the value of the sugar produced. It is interesting to note that the social opportunity cost of land is somewhat lower than its private opportunity cost. This result occurs because part of the private return to land in cultivation of alternative crops arises from input subsidies for those crops.

For most sugar growers, sugar cultivation was also privately unprofitable. The only exceptions were the first and second ratoon crops in dryland areas (T II and T III). Once the investment in planting cane in dryland areas is sunk, the private return to ratoon crops is positive. Private profitability is less negative than social profitability as a result of transfers to producers. On the inputs side, the policy of maintaining low prices of chemical inputs, especially fertilizer, to encourage food crop production has been viewed as a major incentive policy for agricultural growth in Indonesia.⁶ For example, the fertilizer subsidy was approximately 30% for urea and 54% for TSP in 1986. Cane producers benefitted from these subsidies (table 5). The major type of fertilizer used in cane production is ammonium sulfate (AS). In 1986, the farm-gate price was 125 rupiah (Rp) per kilogram, while the world price was Rp 196 per kilogram, which implies a subsidy of Rp 49,000 per hectare for S I farmers and slightly smaller amounts for other technologies.

⁵Social profitability accrues to the entire system, not to an element of it. However, to make the social/private cost comparison at the farm level, the social revenue of production is arbitrarily taken to be the farm-level equivalent of the world price times farmers' share of sugar plus the world price of molasses times farmers' share of molasses.

⁶Some observers of Indonesian agriculture have argued that at least a part of the fertilizer subsidy was necessary to offset a market failure in the provision of information about the profitability of the new rice technologies. For the analysis in this paper, all of the fertilizer subsidy is considered a market distortion.

The biggest government direct subsidy on inputs came in the form of the credit subsidy. TRI farmers have access to 12% credit, while the social interest rate is 20% per annum. This differential provides a Rp 146,000 per hectare subsidy for the S I crop, with the T III crop as the lowest with Rp 60,000 per hectare. For all technologies, the credit subsidy alone is substantially larger than the subsidy on fertilizers. Together, the credit and fertilizer subsidies are the prime determinants of the transfer on the inputs side.

The principal determinant of transfers to the farm production activity is the difference between world and domestic prices. In 1986/1987, farmers received a provenue price of Rp 467.50 per kilogram for their share of sugar produced (approximately 62%).⁷ The CIF price for sugar in 1987 was Rp 329 per kilogram (approximately 1C¢/lb), equivalent to a mill-gate social price of Rp 329 per kilogram (after converting to social costs and subtracting the social value of transport costs). For one hectare of S I cane, private gross revenue was Rp 2.73 million, while social gross revenue was only Rp 2.01 million.

The aggregate effects of government policies on sugar production can be calculated by multiplying the per hectare results by the number of hectares in each type of cane production (table 6). In 1986/87, the foregone social net revenue was Rp 248 billion. Farmers bore part of this cost in the form of a private loss of Rp 115 billion. The remainder was borne by consumers and the government in the form of higher consumer prices and government subsidies on various inputs.

To gain further insight into the effect of the opportunity cost of land, it is useful to decompose the aggregate PAM into two matrices, one each for cane cultivation on irrigated and on dryland areas (table 7). Social profitability in the irrigated areas is negative primarily because of the high social opportunity cost of land. For dryland areas, social profitability is still negative, but private profitability is positive. Even though the first crop in the dryland areas has negative profit, the positive profitability of the ratoon crops more than compensates. This result is supported by anecdotal evidence that sugar production in dryland areas is privately profitable and that it is quite common in those areas to find sugar that has been ratooned more than once.

⁷Two percent of farmers' share is received in kind and valued at the ex-factory price.

Net effects	599	598	370	504	463

Source: Own estimates; data appendix available from authors.

Note: Some numbers do not add up because of rounding errors.

^a S I—planted cane, grown on irrigated areas; S II—first ratoon cane, grown on irrigated areas; T I—planted cane, grown on dry land areas; T II—first ratoon cane, grown on dry land areas; and T III—second ratoon cane, grown on dry land areas.

^b Private revenue is the provenue price times 98% of farmers' share of sugar, plus ex-factory price times 2% of farmers' share, plus domestic price of molasses times farmers' share of molasses.

^c Social revenue accrues to the whole production and processing chain. For this table, social revenue of production is arbitrarily taken to be the farm-level equivalent of the world price times farmers' share of sugar, plus world price of molasses times farmers' share of molasses.

Processing

The total private cost of milling cane (excluding the cost for the cane) was Rp 383 billion (table 8), while total revenue was only Rp 372 billion, resulting in a private loss of Rp 11 billion. The social cost of sugar processing was substantially larger than the private cost. The principal source of this difference was the capital subsidy to the

mills of Rp 69 billion. The private cost of capital to the mills was assumed to be only 10% (because they had access to foreign, low cost loans for rehabilitation) while the social cost was 20%. Social revenue came mainly from the mills' share of sugar output (37.2%). Transfer to the mills on the revenue side was Rp 75 billion. The net transfer to the mills was Rp 159 billion.

Post-Factory Transportation

The final category of cost is for transportation from factories to the wholesale level. The average cost of transporting a kilogram of sugar was Rp 25 (Rosegrant et al., p. 4.42); the total private cost of transportation from mills to the wholesale market is Rp 44 billion. The Indonesian input-output table for 1983 was used to break down the costs into the various categories (table 9).

The Indonesian Sugar Policy Analysis Matrix

The net effects of policy in the sugar system are shown in the PAM in table 10. In terms of both private and social profitability, sugar production in Indonesia is unprofitable. (See Pearson et al.

for a similar result.)⁸ The social loss is Rp 465 billion, about 1% of agricultural value added. Farmers, consumers, and the government all

⁸Strictly speaking these results are for Javanese production only. See earlier comments about the role of production off-Java.

Table 10. Policy Analysis Matrix for the Sugar Commodity System in Indonesia, 1987 (billion rupiah)

	Labor	Land	Capital	Tradables	Total Cost	Revenue	Profit
Private	255	421	122	290	1,088	961	-127
Social	255	373	210	324	1,162	698	-465
Divergences	0	48	-88	-34	-75	263	338

subsidize the production of sugar. For farmers, the transfers received from subsidized capital, inputs, and higher-than-world sugar prices are offset by the losses from not being able to grow more profitable alternative crops. Consumers pay Rp 263 billion more than they would if the domestic sugar price were equal to the world price. The government loses Rp 88 billion in the form of a capital subsidy to the mills and TRI farmers, and Rp 34 billion for subsidies on chemical inputs.

Conclusions

Food policy analysts normally think in terms of trade-offs between consumers and producers, but Indonesian sugar policy does not fit that model. Instead, producers, consumers, and the government budget all have paid to help the government advance its objective of self-sufficiency in sugar. The policy analysis matrix is an effective tool to sort out the conflicting effects arising from the various policy instruments used to achieve that objective. Other measures such as the DRC or the EPC would illuminate only part of the picture.⁹ For example, the DRC would reveal the negative social profitability of cane production but would not make clear the complex set of transfers that arise. The EPC would indicate the impact of product market transfers but not show factor market transfers or measure social profitability.

Policy makers know what policy goals are and what policy instruments are being used. The PAM provides a framework in which to measure the costs and benefits of those policy instruments to various market participants and to the economy, and the results are presented quickly and efficiently. At the same time, the limitations of the PAM should be made clear. The PAM typically

uses fixed input-output coefficients, so it is not possible to use the PAM directly to indicate producer or consumer responses to policy changes that reduce distortions. Transfers to consumers and producers measured by the PAM are exactly equal to the more familiar consumer and producer surplus measures only under restrictive assumptions. However, the transfers are roughly equal to the rectangles associated with traditional surplus calculations.

The instruments used to implement Indonesian sugar policy are complicated and contradictory, with some partially offsetting the effects of others. The net effects are unusual, even by the standards of sugar policy around the world. Domestic output prices are above world prices and domestic input prices are lower than world prices, a situation that normally results in excess profits for cane producers. In spite of these price policies, Javanese farmers must be compelled to grow cane. Because the profitability of alternate crops is so much higher than cane, even substantial government and consumer transfers to producers were not enough to induce farmers to grow cane willingly.

Until 1989, Indonesia was essentially self-sufficient in sugar, but this basic policy goal was met at substantial cost to producers, consumers, and the government. Farmers, forced to grow cane on irrigated land, had negative private profits, and the Indonesian economy lost because the social cost of cane production (and milling) was much higher than its social value. A large share of cane production is on irrigated land that otherwise would be used to grow crops, primarily rice, with much higher profit both privately and socially. By mandating cane production, the potential for socially profitable rice self-sufficiency (the most important Indonesian agriculture policy goal) is reduced. The government also lost financially because of the credit and fertilizer subsidies, which reduce the losses incurred by farmers and the milling firms. Consumers lost because domestic prices were set higher than world prices, again to reduce the

⁹These measures can be calculated easily from the values in the PAM. See Monke and Pearson.

losses incurred by farmers. Only a few cane growers using dry land benefitted.

Indonesia's sugar policies reflect the history of sugar in that country. Succeeding generations of policy makers have made incremental changes to the existing policy set rather than start anew. For example, the most recent change—the TRI program, which ended land rental by the mills and mandated that production be managed by smallholders on their own land—left in place many of the policies of the past. As a result, a complex web of policies has grown up with a correspondingly complex underpinning of interest groups (e.g., employees and owners of socially unprofitable sugar mills, sugar cane dealers and farm managers, sugar traders) that benefit from various aspects of the policies. Any change either must balance the interests of the current beneficiaries with those of the much more numerous sugar consumers and producers who would gain from reform, or else result from a powerful, exogenous shock.

Education and Innovation Adoption in Agriculture: Evidence from Hybrid Rice in China

Justin Yifu Lin

This paper uses the diffusion of F_1 hybrid rice as a case for examining the effects of education on the adoption of new technology in China. A simple behavioral model that treats the adoption of hybrid rice as a portfolio selection problem is presented. The implications of the model are tested with farm-level data collected from a sample of 500 households in Hunan Province. The results from a dichotomous probit model and a two-limit tobit model are consistent with the hypothesis that education has a positive impact on the adoption of new technology.

Key words: China, economic development, education, portfolio-selection model, technology diffusion.

The continuous creation and introduction of new technology has been used as a standard for distinguishing a modern agricultural system from a traditional one (Schultz 1964). However, the introduction of many new technologies has met with only partial success, as measured by observed rates of adoption. Constraints to the rapid diffusion of a new technology may arise from many sources, such as lack of credit, inadequate farm size, unstable supply of complementary inputs, and so on (Feder, Just, and Zilberman). This paper examines the role of education in a farm household's decision regarding adoption of F_1 hybrid rice seed in the context of the Chinese economy.

A new agricultural technology may reflect high yield, low cost, or other desirable traits. However, the changes in the production process involved in the adoption of a new technology may

bring risks resulting from imperfect information and the possibility of committing errors. Because education enhances one's ability to receive, decode, and understand information, Schultz (1964, 1975) and Nelson and Phelps, among others, have hypothesized that education may facilitate the diffusion of new technology. That is, farmers with a relatively high level of education may have a higher probability of adopting new technologies than those with relatively little education.

A number of empirical studies have examined the linkage between adoption of new agricultural technology and education. Some of the evidence is summarized by Feder, Just, and Zilberman. In those studies, the likelihood of adopting a new technology was found to be positively related to the education level of farmers. A recent study by Duraisamy also found that in India the level of using high-yielding rice varieties is positively related to education level. The above theory and evidence suggest that a farmer's education level may be an important factor in the adoption of F_1 hybrid rice in China.

China is the only country in the world in which F_1 hybrids are commercially used in production. Several studies have estimated the profitability of hybrids as compared to conventional varieties (He et al. 1984; He, Zhu, and Flinn 1987a, b). The yield advantage of hybrids over conventional varieties is about 15%. Because China's economy is centrally planned, governmental intervention has often been used in promoting cer-

The author is also indebted to two anonymous referees for helpful comments on an earlier draft of this paper.

tain technologies. As a result, just how important economic considerations are in the adoption decision regarding F_1 hybrids at the farm level is a controversial question (Wiens; Barker and Herdt, p. 61). An earlier study of my own (Lin 1991), using aggregate panel data, found profitability to be an important factor in explaining differences across regions and over time in the diffusion of hybrids after the household-based farming system reform, but not in the prereform period.¹ However, because of the aggregate nature of the data set used in that study, direct conclusions about the role played by education and other household characteristics could not be drawn.

For the purpose of this study, cross-section production data collected at the end of 1988 from a sample of 500 households are used. The main purpose is to determine the role of education in a household's decision regarding adoption and intensity of use of F_1 hybrids. In addition, other potentially relevant variables, such as the farming experience and sex of the household head and the availability of credit, are included.

The paper is organized as follows: The next section presents a simple behavioral model, which treats the adoption decision as a portfolio selection problem. The model is followed by a description of the areas covered by the study and the data set. The subsequent section presents the empirical analysis. The last section summarizes the results and discusses their implications.

A Portfolio Selection Model of Technological Adoption

In order to analyze the impact of education on the adoption decision regarding F_1 hybrid seeds, this section constructs a formal behavioral model in which the adoption of new technology, represented by the use of F_1 hybrid seed, is treated as a portfolio selection problem. The objective of a farm household is to maximize its expected utility. Following the convention of portfolio selection literature, a household is assumed to care only about the mean and variance of its income.² For simplicity, a farm household grows only a single crop, rice, on a unit of land. There

are two alternative technologies—conventional rice (CR) and F_1 hybrid rice (HR). CR is assumed to have a low yield, but the output is certain to each household. The output level, however, may be different from household to household as a result of the difference in some household characteristics. HR, on the other hand, has a higher expected yield but the output level is uncertain to each household. The variance of the output level will be assumed to depend on the i th household head's education level and other household-specific variables that affect the household's ability in dealing with new technology.³

Following Jamison and Lau's convention (p. 197), if CR is used on all of the i th household's land, its income can be written as a function of variables representing the economic environment and a specific household factor, in the form

$$(1) \quad Y_{i,C} = M_C(E) + \epsilon_{i,C},$$

where E is a vector of independent variables representing the prices of rice, seeds, chemical fertilizers, pesticides, and so on, and $\epsilon_{i,C}$ is a variable representing the i th household's specific capacity for producing CR.⁴ Similarly, the mean income from using HR on all its land can be written as a function of the same independent variables, and a specific household factor, in the form

$$(2) \quad Y_{i,H} = M_H(E) + \epsilon_{i,H}.$$

The variables $\epsilon_{i,C}$ and $\epsilon_{i,H}$ cannot be directly observed, but it is assumed that their joint distribution over the whole population can be described by a probability density function. Therefore, the i th household's mean income with r_i proportion of its land producing HR can be expressed as

$$(3) \quad Y_i = \{M_C(E) + \epsilon_{i,C} + r_i[D(E) + (\epsilon_{i,H} - \epsilon_{i,C})]\},$$

where $D(E) \equiv M_H(E) - M_C(E)$.

If a household allocates all its land to produce CR, there will be no variance in its income, as the output level of CR is assumed to be constant to each household. If a household allocates all

¹ Farming activities were organized in a collective team system prior to the farming institutional reform in 1979. The collective system was replaced by an individual household-based system by 1983. For a theoretic and empirical study of this reform, see Lin (1988).

² This assumption requires that the utility function be quadratic, or/and that the outputs of new as well as old technologies have a normal distribution.

³ These assumptions imply that the adoption of CR is riskless, and that HR is risky.

⁴ That is, the first component, $M_C(E)$, is common to each household, and the second component, $\epsilon_{i,C}$, differs from household to household. The difference in the second component may arise from several sources, like the quality of irrigation, fertility, and other microphysical conditions of the household's landholding, the experience and ability of the household members, and so on.

its land to produce HR, the variance in the household's income will be assumed to have the following functional form:

$$(4) \quad V_i = V_{i,H}(e_i, Z_i, E),$$

where e_i is the i th household head's education level; and Z_i is a vector of other household-specific variables, such as the availability of credit and extension service to the household.⁵ If a household allocates r_i proportion of its land to produce HR, the variance in its income will thus be

$$(5) \quad V_i = r_i^2 \cdot V_{i,H}(e_i, Z_i, E).$$

From expression (5), we find that the variance of a household's income is positively related, and increases at an increasing rate, to the proportion of land that the household allocated to HR.

For simplicity and ease of interpretation, the utility function is assumed to be separable, and to have the following specific form:

$$(6) \quad U_i = Y_i - C(V_i) = Y_i - C(r_i, e_i, Z_i, E),$$

where $C_1 > 0$, $C_{11} > 0$, $C_{12} < 0$, and $C(0, e_i, Z_i, E) = 0$.

The specifications of $C(\cdot)$ in the second line of expression (6) imply that, given other variables, the utility loss increases and at an increasing rate with the ratio of land allocated to HR, that education reduces the utility loss of adopting HR, and that there is no utility loss if HR is not adopted. These characteristics can be justified by the previous assumptions that the income variance increases and at an increasing rate with the proportion of land used in HR, education reduces the variance of HR output, and

ity in producing CR and HR, and other exogenous variables in the household as well as economy, the household will allocate its land to HR in a way that its utility is maximized.

The Probability of Adoption

Before solving for the optimal proportion of land used for HR, r_i^* , we will first consider the probability that the i th household will allocate part of its land endowment to HR, that is, r_i will be greater than zero. Expression (7) indicates that the necessary condition for $r_i > 0$ is $r_i \cdot [D(E) + \epsilon_{i,H} - \epsilon_{i,C}] - C(r_i|e_i, Z_i, E) > 0$. Therefore, whether a household adopts HR depends only on the value of $r_i \cdot [D(E) + \epsilon_{i,H} - \epsilon_{i,C}] - C(r_i|e_i, Z_i, E)$. As shown in figure 1, the necessary and sufficient condition for $r_i > 0$ is

$$(8) \quad C_1(0|e_i, Z_i, E) < D(E) + \epsilon_{i,H} - \epsilon_{i,C},$$

where $C_1(0|e_i, Z_i, E)$ is the first derivative of $C(r_i|e_i, Z_i, E)$ evaluated at $r_i = 0$. The adoption indicator of the i th household, A_i , takes the value of

$$(9) \quad A_i = \begin{cases} 1 & \text{if } C_1(0|e_i, Z_i, E) < D(E) + \epsilon_{i,H} - \epsilon_{i,C}, \text{ HR is adopted, and} \\ 0 & \text{if } C_1(0|e_i, Z_i, E) \geq D(E) + \epsilon_{i,H} - \epsilon_{i,C}, \text{ HR is not adopted.} \end{cases}$$

Thus, the probability that a household drawn randomly from the population, with education of household head, other characteristics and environment variables given, would adopt HR equals

$$\begin{aligned} P_i &= \Pr(A_i = 1) = \Pr[C_1(0|e_i, Z_i, E) < D(E) + \epsilon_{i,H} - \epsilon_{i,C}] \\ &= \Pr[C_1(0|e_i, Z_i, E) - D(E) < \epsilon_{i,H} - \epsilon_{i,C}]. \end{aligned}$$

the output of CR is constant. The optimization problem for a household can thus be expressed as follows:

$$(7) \quad \begin{aligned} \text{Max}_{0 \leq r_i \leq 1} \quad & U_i(r_i|e_i, \epsilon_{i,C}, \epsilon_{i,H}, Z_i, E) \\ & = \{M_C(E) + \epsilon_{i,C} + r_i \cdot [D(E) + (\epsilon_{i,H} - \epsilon_{i,C})]\} - C(r_i|e_i, Z_i, E). \end{aligned}$$

This expression postulates that, given the i th household head's education level, specific abil-

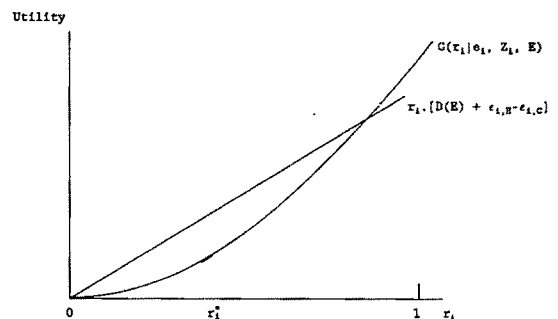

Figure 1. The optimal land allocation to hybrid rice

⁵ Because education enhances the ability of using new technology, the variance of HR output will be postulated to be inversely related to the educational level of the household head.

This probability depends on the difference of the functions $C_1(0|e_i, Z_i, E)$ and $D(E)$ and $\epsilon_{i,H} - \epsilon_{i,C}$. $C_1(0|e_i, Z_i, E)$ is specified as a linear function of e_i ; that is,

$$C_1(0|e_i, Z_i, E) = a_0 e_i + a_1 Z_i + a_2 E,$$

where a_0 is an unknown parameter, and a_1 and a_2 are both row vectors of unknown parameters. Similarly, $D(E)$ is a linear function of E ,

$$D(E) = bE,$$

where b is a row vector of unknown parameters. We will denote the difference in the individual household factors as ϵ_i ; that is,

$$\epsilon_{i,H} - \epsilon_{i,C} \equiv \epsilon_i.$$

Then, the probability of the i th household adopting HR equals

$$(10) \quad P_i = \Pr(A_i = 1) = \Pr[\epsilon_i < bE - a_0 e_i - a_1 Z_i - a_2 E] \\ = F(b'E - a_0 e_i - a_1 Z_i),$$

where $b' = b - a_2$, and $F(\cdot)$ is the cumulative distribution function.

As shown, the probability of the i th household adopting HR seed is the value of the cumulative distribution function of F evaluated at $b'E - a_0 e_i - a_1 Z_i$. The exact distribution of F depends on the population distribution of the random variable ϵ_i . If ϵ_i is identically and independently distributed as the normal distribution over the population, the unknown parameters b' , a_0 , and a_1 can be estimated by the probit regression model, which yields consistent and asymptotically efficient estimates. Since $C_{12} < 0$ implies that $a_0 < 0$, a larger e_i thus implies a higher probability of adopting HR seed.

Optimal Adoption Intensity

The i th household's optimal proportion of land used in the production of HR can be obtained by solving expression (7). The first-order condition for an optimum requires

$$(11) \quad D(E) + \epsilon_{i,H} - \epsilon_{i,C} - C_1(r_i|e_i, Z_i, E) = 0.$$

Equation (11) implies that, for the optimality to hold, the decision maker equates the utility gain from adopting HR with the utility loss resulting from adopting this new technology at the margin. The second-order condition requires that $-C_{11} < 0$, which holds according to the basic assumptions.

The effect of education on the optimal proportion of land used for HR is implicitly defined in equation (11). From the implicit function theorem, we can obtain the following relation:

$$(12) \quad dr_i/de_i = -C_{12}/C_{11} > 0.$$

The optimal proportion of a household's land used for HR is thus implied in expression (11). To be specific, the optimal proportion can be expressed in a functional form as follows:

$$r_i^* = r(e_i|\epsilon_i, Z_i, E),$$

where $\epsilon_i = \epsilon_{i,H} - \epsilon_{i,C}$, as previously defined, is assumed to be identically and independently distributed as the normal distribution over the population. We will assume that the function is linear in e_i , Z_i , and E , that is,

$$(13) \quad r_i^* = c_0 e_i + c Z_i + dE + \epsilon_i,$$

where c_0 is an unknown parameter, and c and d are row vectors of unknown parameters. Because $0 \leq r_i \leq 1$, the dependent variable r_i is censored. The tobit regression model with lower bound zero and upper bound 1 will yield consistent and asymptotically efficient estimates of the unknown parameters in expression (13).

The discussion so far focuses solely on the effect of a household head's education on the probability and intensity of adopting HR. It is also possible to investigate the impacts of other household characteristics and environmental variables under the present framework. For example, an increase in the price of rice will increase the relative profit of HR over CR and, therefore, increase the probability and intensity of adopting HR. Changes in the price of purchased inputs may also affect the probability and intensity of adopting HR if the requirements of purchased inputs differ between CR and HR. The availability of credit may facilitate adoption if more purchased inputs are used for HR and a household's liquidity becomes a constraint. Furthermore, most farm households are obliged to sell a certain quota of rice at below-market price to the government. In cases where the quota is a binding constraint, a household may adopt hybrid rice simply for its higher yield, even though it may not be as profitable as conventional rice. However, a full-length discussion of the impacts

of these other variables is beyond the purview of this paper.⁶

The Data and Study Setting

The data come from a cross-section survey of 500 households in five counties in Hunan Province which was carried out during December 1988 and January 1989. Hunan Province is located on the middle reaches of the Yangtze River in South China. It has a semitropical climate. The average temperature is 4–7 °C in January and 26–30 °C in July, with 260–300 frost-free days. Annual rainfall is about 1,300 millimeters to 1,700 millimeters. Most of the rainfall is concentrated in May, June, and July. Of the total land area of 211,000 square kilometers, mountains make up 51.2%, hills 29.2%, plains 13.1%, and water surface 6.4%. The province has 2.56 million hectares of cultivated land, 82% of which is irrigated. The per capita cultivated area is 0.05 hectare, below the national average. The total population is 5.8 million, of which 4.8 million is agricultural. From the proportion of agricultural population in total population, and from the per capita gross values of agricultural output and industrial output, Hunan can be considered in China to be a predominately agricultural province (see table 1). Rice is its most important crop. In 1987, 57% of the total cultivated acreage (or 82% of the grain acreage) was planted with

rice, and, of the rice acreage, 46.5% was planted with hybrid seed.

The province is divided juridically into 105 counties in three types of geographic setting—lake-plain, hill, and mountain. Among the five counties in the data set, the first two—Tiaojiang and Xiangxiang—are selected from the hill region, the next two—Nanxian and Anxiang—from the lake-plain region, and the last one—Zhijiang—from the mountain region. These five counties were selected from the provincial sample of thirty-four counties surveyed annually by the State Investigation Team. Table 1 indicates that the 1988 per capita GNPs of these five counties were all lower than the provincial average, but that their per capita gross values of agricultural output were all higher than the provincial average. However, their rice economies are considered typical, and their agricultural conditions and infrastructure are representative of their respective regions.

Samples of 100 households each from these five counties were surveyed. These households were all included in the random samples surveyed by the State Investigation Team. Table 2 summarizes the key characteristics of the samples in each of the five counties. While households in the two hill counties, Tiaojiang and Xiangxiang, had the highest per capita income in 1988, households in the two lake-plain counties, Nanxian and Anxiang, had the largest farm size. The main reason for the large farm size in the lake-plain region is that a substantial amount of cultivated land has been newly reclaimed from Dongting Lake, one of the five largest lakes in China.

Education in this study refers to a household head's years of formal schooling, including general and vocational training. China's school sys-

⁶ The above model is obviously oversimplified. The framework could be further developed in many directions; however, the simplest form of the model is adopted in order to illustrate clearly its implications. For other models that treat technology adoption as dichotomous choice, see Jamison and Lau; as a portfolio selection problem, see Feder, and Just and Zilberman.

tem consists of primary, secondary, and tertiary level. Because of a strong urban bias in the school system, students in rural areas are at a disadvantage to compete with students in urban areas. Therefore, the dropout rate in rural primary school is high, and only a small portion of primary school graduates continues higher education.⁷ In the samples, only one household head completed college education and 93.3% of household heads have less than 10 years of schooling. The average years of schooling is 5.52, about the level of a primary school graduate, with a large variation across age cohorts. The average for the cohort of household heads with age less than 30 is 7.85, while for the cohort with age 50 or older the average is 3.91. The average years of schooling is 6.39 for the cohort of thirties and 5.37 for the cohort of forties. Thus the younger a household head is, on average, the better is his/her education.

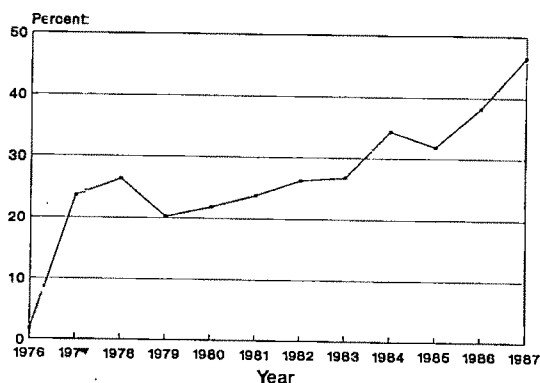

F_1 hybrid seeds were released to farmers in 1976. The price of hybrid rice matched the price of conventional rice. However, the price of hybrid seed was set officially to be ten times the price of conventional seed because initially the seed field produced about one-tenth the seed of a conventional rice field.⁸ Increase in seed costs, however, is mitigated by reduced seed requirements because of low plant density necessary in hybrid rice production.⁹

The yield of F_1 hybrids is reported to be about

20% higher than the conventional rice. In the first two years, the diffusion of hybrid rice in Hunan was very rapid, but it declined sharply in 1979 and stagnated until 1983 (see fig. 2). Several factors may contribute to this fluctuation and stagnation. Substantial government intervention was used at the beginning stage. Because rice-growing environments were diverse but the range of available hybrid varieties initially was limited, crop failures occurred in a number of areas owing to lack of resistance to local diseases. In addition, the growing time of the early-released hybrids was rather long (135 days), and the cooking quality was also a concern. However, most of the aforementioned problems were largely solved by 1988, the time of the survey.¹⁰

The new household-based farming system was introduced in the study areas during 1981–82. Table 3 compares the percentages of households in each county that adopted and did not adopt

¹⁰ The increase in the diffusion of hybrid rice after 1983 can partly be attributed to the improvement in a farmer's incentive for acquiring new innovation resulting from the change from the collective system to the household-based farming system (Lin 1991).

**Figure 2. Diffusion of hybrid rice in Hunan**

⁷ For an informative discussion of the issues and changes in China's rural education, see Perkins and Yusuf, chap. 8.

⁸ The production of F_1 hybrid seed involves a complicated three-line method: (a) locating a cytoplasmic male-sterile parent plant; (b) crossing it with a maintainer line to produce offspring with sterility but with desirable genetic characteristics; and (c) crossing these seeds with a "restorer" line to produce F_1 seeds with normal self-fertilizing power. Initially the yield of hybrid seed fields was very low. The yield has been improved and reached one-third to one-half the yield of a regular field but the price ratio is still maintained.

⁹ Because of high-tillering rate, F_1 hybrids require only one-third to one-fourth of conventional rice's seeding rate.

Table 3. Changes in Adoption of Hybrid Seeds

	Tiaojian (N = 100)	Xiangxiang (N = 100)	Nanxian (N = 100)	Anxiang (N = 100)	Zhijiang (N = 100)

Nonadopter	63	90	96	80	48
In 1988					
Adopter	78	67	64	93	99
Nonadopter	22	33	36	7	1

F_1 hybrids at the time when the new farming system was introduced and in 1988. Except in Zhijiang, the majority of households did not adopt hybrids when the institutional change occurred. In contrast, most households in all five counties adopted hybrids in 1988. The higher incidence of early adoption in Zhijiang county probably reflects the fact that most households in Zhijiang grow only one crop of rice a year, while in the other four counties most households grow two crops of rice annually. Therefore, the early-released hybrids, with a rather long maturation period, could be integrated more easily into the cropping system in Zhijiang.

Among the 500 households in the sample, 78% reported to have increased their hybrid-planted acreage, while only 4.2% reported that their hybrid acreage was reduced. The main reason reported for increases in hybrid rice acreage was improvement in yield advantage (384 out 390 households reported this reason). The releases of new hybrid varieties with suitable maturation period, however, should have also contributed to the increase. Our survey shows that the actual growing time in 1988 for early, middle, and late hybrids averaged, respectively, 111 days, 152 days, and 122 days, compared to 109 days, 149 days, and 125 days for conventional early, middle, and late rice.

As for government support for the adoption of F_1 hybrids, 21.2% of households reported that chemical fertilizers were used as an award when the hybrids were first promoted, and another 2.6% reported that hybrid seed was subsidized. Currently, none of the surveyed households reported seed subsidies and only 4.4% of the households reported having fertilizer supports.¹¹

The survey also asked about cooking quality of hybrid rice. The responses of the sample households indicate that this is no longer an is-

sue. Among the 319 households growing both hybrids and conventional rice, 48% reported eating conventional rice for daily meals, while the other 52% reported eating hybrid rice. As for the rice used for special occasions like entertaining guests and celebrating festivals, 25.4% reported to prefer conventional rice, 39.8% to prefer hybrid rice, while the remaining 34.8% reported having no preference.

Of the 500 households surveyed, 495 devoted part of their land to rice. Detailed information on the number of households using hybrid and conventional seed in each of the five counties in 1988 is reported in table 4. While only a few (thirteen) among the 495 households planted hybrids in the early rice season, the majority of households adopted hybrid seed either in the middle season if only one crop of rice is grown or in the late season if two crops of rice are grown each year. A substantial portion of the households in each county planted both hybrid and conventional rice in a single crop season. This practice will enable us to investigate not only the problem of dichotomous choice but also the optimal allocation of land to the production of hybrids.

The reason for early hybrids not being adopted by most households may arise from the fact that the yield advantage of early hybrids with suitable maturation period was not significant compared to early conventional varieties. Table 5 reports the means and standard deviations of inputs and outputs for hybrid and conventional rice from the samples. While the mean yields of hybrids were significantly higher than those of conventional varieties for middle and late rice, the difference is not statistically significant for early rice. Hybrid rice's yield advantages are partly offset by added requirements for chemical inputs and more expenditures for seed. As indicated in table 5, significantly more chemical inputs (chemical fertilizers and pesticides) were devoted to hybrids as compared to conventional varieties. Also, although cultivation of hybrids

¹¹ This response may underreport the government's function in the promotion of F_1 hybrid rice, as government supports are mainly given to the seed research and distribution system and not directly to individual households.

Table 4. The Adoption of Hybrid and Conventional Rice in 1988

	Tiaojian (N = 100)	Xiangxiang (N = 100)	Nanxian (N = 97)	Anxiang (N = 99)	Zhijiang (N = 99)
Early Rice					
Hybrid	4	7	0	0	2
Conventional	98	98	92	98	6
Both	2	5	0	0	0
Middle Rice					
Hybrid	0	1	8	8	99
Conventional	0	0	11	9	14
Both	0	0	0	2	14
Late Rice					
Hybrid	79	67	63	90	9
Conventional	35	49	78	51	0
Both	14	18	46	43	0

required only about one-third to one-fourth as much seed as conventional varieties, the price of hybrid seed is fixed as ten times that of conventional seed. Therefore, the advantage of growing hybrids compared to conventional varieties depends largely on the prices of chemical inputs and seed, even for middle and late rice. However, hybrid rice does not require more labor input than conventional rice.

Empirical Analysis

Functional Form Specification

In the theoretical section, it was argued that the probability as well as the intensity of adopting F_1 hybrid seeds in rice production for a randomly selected household are functions of the

household head's education, and other variables representing the household's characteristics and the economic environment. It is clear from the theoretical model that the functions for the dichotomous choice and for the optimal adoption decision should have the same set of explanatory variables. Table 6 presents the definitions, means, and standard deviations of the variables which will be used as regressors in the empirical analysis. Variables 1 to 4 are county dummies that represent some county-specific characteristics, which affect the adoption decision but are not observable to researchers.¹²

¹² The county dummies capture the effect of differences in a county's topography, rainfall, temperature, and other physical variables on a household's adoption decision. Because hybrid seed production, distribution, and extension services are organized by each county government, the county dummies will also capture the effect of differences in these government-provided services.

Table 5. Means and Standard Deviation—Hybrid and Conventional Rice

	Early Rice		Middle Rice		Late Rice	
	Conv. (N = 392)	Hybrid (N = 13)	Conv. (N = 34)	Hybrid (N = 116)	Conv. (N = 213)	Hybrid (N = 308)

Table 6. Variable Definitions, Means, and Standard Deviations

Dependent variables:		
(1) <i>AHR</i>	Adoption dichotomous = 1 if middle or late hybrid rice is adopted, 0 otherwise	.82 (.39)
(2) <i>PHR</i>	Percentage of middle and late rice area grown with hybrid seeds	.69 (.40)
Independent variables:		
(1) <i>C2</i>	County dummy variable = 1 if Nanxian County, 0 otherwise	.20 (.40)
(2) <i>C3</i>	County dummy variable = 1 if Anxiang County, 0 otherwise	.20 (.40)
(3) <i>C4</i>	County dummy variable = 1 if Zhijiang County, 0 otherwise	.20 (.40)
(4) <i>C5</i>	County dummy variable = 1 if Xiangxiang County, 0 otherwise	.20 (.40)
(5) <i>Ps</i>	Price of hybrid rice seed (Yuan/kg)	4.07 (.63)
(6) <i>Pf</i>	Price of chemical fertilizer (Yuan/kg)	.41 (.49)
(7) <i>Pp</i>	Price of pesticide (Yuan/kg)	10.06 (2.49)
(8) <i>LAND</i>	Land area cultivated (in mu, 1 ha = 15 mu)	6.46 (2.97)
(9) <i>LABOR</i>	Number of adults	4.39 (1.22)
(10) <i>CAPITAL</i>	Value of capital equipment (in Yuan)	459.22 (653.24)
(11) <i>CR</i>	Credit dummy = 1, if formal credit used in the previous two years, 0 otherwise	.41 (.49)
(12) <i>Quota</i>	Rice procurement quota dummy variable = 1 if quota exists, 0 otherwise	.97 (.16)
(13) <i>Avedu</i>	Average education level of other adult household members (in years)	5.18 (2.27)
(14) <i>Job</i>	Job dummy of household head, = 1 if nonfarm, 0 if farm	.10 (.30)
(15) <i>Sex</i>	Sex of household head, = 1 if female, 0 otherwise	.04 (.19)
(16) <i>Agryrs</i>	Household head's experience in agriculture (in years)	23.66 (11.61)
(17) <i>Eduhead</i>	Education level of household head (in years)	5.49 (2.58)

Variables 5 to 7 are price variables, representing the economic environment. Theoretically, the prices of seed, fertilizer, and pesticide relevant to the decision to adopt hybrid seeds should be expected prices. Because data on expected prices are not available, the actual prices a household paid were used as proxies for expected prices.¹³ If significant differences exist between expected prices and actual prices, the estimates of parameters may be biased. The price of rice is not included in the list because no cross-sectional variation in rice price existed. Because the information on wage, rent, and interest rate are not available, wage, rent, and interest rate are not included either.

¹³ The prices are derived from each household's actual expenditures on seeds, fertilizers, and pesticides, dividing by the quantities of seeds, fertilizers, and pesticides. Because some portion of each of the inputs was rationed and some was purchased from markets, the derived prices are the average prices paid by a household.

Variables 8 to 13 represent the household-specific characteristics, including endowments in landholding, labor, and capital, dummies for credit availability and state rice procurement quota, and the average education level of adult household members (excluding the household head).¹⁴ The last group of variables was the household head's personal characteristics, including dummies for job type and sex, years of experience in agriculture, and years of education.

As for the dependent variables in the analysis, only the adoption decision with respect to middle rice and late rice is considered. Early rice is excluded because the data indicate that adapted

¹⁴ Because information on the availability of credit does not exist, the incidence of taking formal credit in the previous two years was used as a proxy for credit availability. However, this proxy may not reflect actual credit availability because the absence of borrowing may indicate that a household has enough funds of its own.

early hybrids are not yet available. In the dichotomous choice model, a household is considered as an adopter if it grew either middle hybrids or late hybrids. In the model of optimal adoption decision, the dependent variable is the percentage of total rice acreage planted with hybrids in both the middle and late rice seasons.¹⁵

The theoretical model suggests that if the functional forms of $D(E)$ and $C_1(0|e_i, Z_i, E)$ are linear, and the unobservable variable ϵ_i is identically and independently distributed as the normal distribution over the population, then probit is the appropriate method for estimating the unknown parameters in the dichotomous choice model. Similarly, if the functional form of $r(e_i|e_i, Z_i, E)$ is linear in the explanatory variables and ϵ_i has a normal distribution, then the two-limit tobit is the appropriate method for estimating the unknown parameters in the optimal adoption rate equation. Therefore, the probit and tobit model will be applied to estimate the following function:

$$(14) \quad X = \alpha_1 + \alpha_2 C2 + \alpha_3 C3 + \alpha_4 C4 + \alpha_5 C5 + \beta_1 LnFs + \beta_2 LnPf + \beta_3 LnPp \\ + \gamma_1 LnLand + \gamma_2 LnLabor + \gamma_3 LnCapital + \gamma_4 CR + \gamma_5 Quota + \gamma_6 Avedu \\ + \delta_1 Job + \delta_2 Sex + \delta_3 Agryrs + \delta_4 Eduhead + \epsilon_x; \\ X = AHR \text{ (dummy variable for the dichotomous choice) or PHR} \\ \text{(percentage of acreage planted with hybrids).}$$

The price variables and input endowments are the logarithms of their respective quantities. This is because under the assumption of Cobb-Douglas production functions, the logarithmic normalized production function is a linear function in the natural logarithms of the normalized prices and the fixed inputs, and is also linear in the characteristic variables (Jamison and Lau, p. 203).

Empirical Results

The empirical results are presented in table 7. The estimates of coefficients indicate that a household head's education level has a positive effect both on the probability of adoption and the intensity of adoption of F_1 hybrids, as predicted by the theoretical model. The estimates are different from zero at a .1% level of significance in the dichotomous choice model and at a 5% level of significance in the optimal adoption decision model. This evidence gives support in a Chinese context to Schultz's thesis about

the role of education in decisions about the adoption of new technology.

As for the effects of other independent variables on the probability of adopting hybrid seed, the estimates in column (1) indicate that a household head's number of years of experiences in agriculture, the existence of government procurement quota, and the size of a farm's cultivated land also have significantly positive impacts, and the price of hybrid seed has a significant negative impact. Other economic and household characteristic variables do not have a significant effect. The positive impact of farm size on probability of adoption may arise from the economies of scale in acquiring information, credit, and/or hybrid seeds. As for the optimal adoption decision, column (2) of table 7 indicates that, besides a household head's education level and county dummies, a household's capital endowment is the only variable to have significant effect (at 10% level). This result im-

plies that higher investment in fixed inputs increases the proportion of land used in hybrids.

Concluding Comments

This paper has focused on the role of education in a farm household's decision about whether to adopt and the optimal intensity of adoption of F_1 hybrid rice in China. A simple behavioral model was developed in which adoption of new technology was treated as a portfolio selection problem, and the implications of the model were tested with data collected from a sample of 500 households from five counties in Hunan Province. The empirical results are consistent with the implications of the role of education in the theoretical model: A household head's level of education has positive and statistically significant effects on the household's probability and intensity of adopting F_1 hybrid seed.

Because technological change is the main force in agricultural development, the evidence in the paper supports arguments for increasing state investments in rural education in order to facilitate technological change in agriculture. In addition, a farm's size has a positive effect on the deci-

¹⁵ Most households grow either middle or late rice, but not both.

sion to adopt F_1 hybrids. This evidence suggests that the small farm size predominant following the household-based farming institutional reform may pose a restraint to technological change and thus supports the argument for further liberalization in land markets, in order to facilitate consolidation through land market transactions.¹⁶

¹⁶ Although collectivization can solve the problem of farm size, it will reduce a farmer's incentives for farming as well as adopting new technology (Lin 1988, 1991), therefore, collectivization should be excluded as an alternative for solving the problem of farm size.

Incorporating Technological Change in Diffusion Models

Mary K. Knudson

The theoretical and empirical implications of a static and dynamic logistic diffusion model are compared. The dynamic model relaxes some assumptions of the static model by allowing for a flexible adoption ceiling, for changes in the technology, and for disadoption. Both models were used to estimate the diffusion of semi-dwarf wheat varieties in the United States. The dynamic model provides a better fit to the data and provides additional insights into the economic determinants of adoption. In particular, the importance of technological change in other areas (here, in fertilizer) on the diffusion path of an innovation was shown.

Key words: diffusion, semi-dwarf wheat varieties, technological change.

In constructing diffusion models, economists have faced a difficult trade-off. A host of probabilistic frameworks (such as the logistic, probit, and Gompertz; see Griliches 1957, Dixon) permit straightforward estimation of the diffusion trend of an innovation. Ease of estimation, however, comes at the cost of exogenously determined (and often theoretically unjustified) constraints on the rate of adoption and on the point at which the greatest rate of adoption occurs. For example, the logistic model requires the greatest rate of adoption to occur when 50% of the population has adopted the innovation. (For further criticisms of the static diffusion framework, see Mahajan and Peterson 1985.)

A number of the theoretically troublesome assumptions of the static diffusion model have been relaxed by Metcalfe and Gibbons. They present a dynamic diffusion framework which allows the inflection point of the diffusion curve to arise endogenously from the specifications of the model. Their model is of further interest because it depicts explicitly the interactive relationship between research and development and diffusion/adoption. Unfortunately, the data requirements for estimation of the Metcalfe and

Gibbons model are onerous. For example, input costs, including research costs, are required. However, firms are typically unwilling to release such input data.

This paper presents a method for overcoming data limitations in estimating dynamic diffusion models while incorporating additional variables to explain technological change. This methodology has potential application to a variety of diffusion cases, including the adoption of herbicide-resistant crop varieties and low-input agricultural practices. The technique is applied to estimating the diffusion of semi-dwarf wheat varieties (SDWVs). SDWVs are an important yield-increasing biological innovation which has substantially altered the agricultural practices of wheat growers in the United States. To emphasize the value of the dynamic approach, results from the dynamic model will be compared to estimates from a more traditional static diffusion model. As shall be shown, the dynamic model not only provides better estimates of the diffusion of semi-dwarf wheat, but also allows the researcher to determine the impact on the diffusion process of a variety of factors not incorporated within the traditional static model.

This paper is organized as follows. The first section presents the traditional static diffusion model, followed by Metcalfe and Gibbon's generalization to the dynamic case. The third section indicates how market data can be used to yield estimates for dynamic diffusion trends. The fourth section presents the results of a generalized least squares estimation of the traditional static diffusion model and of a dynamic diffu-

sion model for semi-dwarf wheat. Finally, some concluding remarks are made.

A Basic Diffusion Model

The basic diffusion process contains four components: the innovation, the social system in which the innovation is being adopted, channels of communication, and time (Metcalf and Gibbons, Mahajan and Peterson 1985, Bayer and Melone). The innovation component represents the new product being diffused. Inherent in the new product are characteristics that affect its diffusion.¹ A social system is comprised of individuals, organizations, or agencies and their adopting strategies. How a total group of adopters transmits information about an innovation depends on how heterogeneous and cohesive a group of adopters is. The ways that adopters pass on information about an innovation are the channels of communication. Finally, time is the period over which a social system adopts an innovation. Because these four components are present in every diffusion process, any realistic model of diffusion must incorporate them.

In addition, six basic assumptions underlie the diffusion model (See, for example, Mahajan and Peterson 1985.): (A1) The adoption decision is binary. An individual adopts or does not adopt. (A2) A fixed, finite ceiling N^M exists. (A3) The coefficient of diffusion (defined below) is fixed over time. (A4) The innovation is not modified once introduced, and its diffusion is independent from the diffusion of other innovations. (A5) One adoption is permitted per adopting unit and this decision cannot be rescinded. (A6) A social system's geographical boundaries stay constant over a diffusion process.

Incorporating the four components, and assuming (A1)–(A6), the basic diffusion model takes the following functional form (This discussion follows the notation found in Mahajan and Peterson 1985.):

$$(1) \quad dN(t)/dt = g(t) [N^M - N(t)],$$

where $dN(t)/dt$ is the rate of diffusion at time

t , (or, more simply, changes in adoption over time) where t begins at t_0 ; $g(t)$ is the coefficient of diffusion. This coefficient indicates how fast and to what degree adoption occurs. The higher the coefficient, the earlier and greater degree of adoption of an innovation.

The cumulative number of adopters at time t is $N(t)$, or

$$N(t) = \int_{t_0}^t n(t) dt,$$

and $n(t)$ is the number of adopters per time period t ; N^M is the maximum number of adopters in a social system over time t . The number of potential adopters left at time t is $N^M - N(t)$.

While it is clear how innovation and time fit into model (1), the entry of social system and channels of communication are not directly apparent. Their effect is found in the diffusion coefficient, $g(t)$. The specific form of $g(t)$ reflects the influence of the social system and the channels of communication on the diffusion process. For example, when a social system is heterogeneous, fragmented, and lacks communication, $g(t) = b$, where b represents the natural rate of diffusion, i.e., that rate which occurs without any other influence. The resulting diffusion model, $dN(t)/dt = b[N^M - N(t)]$, is called the external influence model. However, when the social system is homogeneous and communicative, $g(t) = bN(t)$, where b still is the natural rate of adoption and $N(t)$ is the impact adopters have on the remaining number of non-adopters, $N^M - N(t)$. The resulting diffusion model,

$$(2) \quad dN(t)/dt = bN(t) (N^M - N(t)),$$

is known both as an internal influence model and as the logistic model; it was used to estimate the diffusion of hybrid corn in Griliches' (1957) seminal piece.

The logistic model imposes an S-shaped, symmetric diffusion trend with a maximum diffusion rate occurring when 50% of the potential cumulative adopters have adopted.² It is based on the premise that diffusion occurs through interpersonal contacts among a group of homogeneous adopters (Mansfield). But not all diffusion models require symmetry around a 50% inflection point. For example, the Gompertz model, $dN(t)/dt = bN(t) (\log N^M - N(t))$, im-

¹ Economists sometimes classify innovations into process and product. A process innovation is an input to a production process. A product innovation is an end product. Generally, product innovations are easier to assess than process innovations because their performance can be measured directly. However, many innovations fall into both categories. That is, one firm's product innovation, say a seed variety, may become a process innovation for another firm. For the purposes of this paper, what category the innovation falls into does not matter as long as it is measurable. For simplicity, product is used.

² For proofs of the logistic model's inflection point and its symmetric diffusion trend, see Mahajan and Peterson 1985, pp. 27–28.

poses an asymmetric trend with the maximum diffusion rate occurring when 37% of the potential cumulative adopters have adopted.³ The assumption here is that although adopters are homogenous, early adopters are relatively more cohesive than middle and late adopters; therefore, they adopt at a faster pace. Dixon used the Gompertz and traditional logistic models to reestimate the diffusion of hybrid corn. He found the Gompertz model was a more accurate measure of hybrid corn diffusion.

Because farmers within a region or country often have similar production practices (homogenous) and communicate well with each other (cohesive), it makes sense to use a traditional logistic model to estimate the diffusion of an agricultural innovation (Mahajan and Peterson 1985). Hence, in this paper, the traditional logistic model is used to estimate the diffusion of semidwarf wheat. Because this model will be compared to a dynamic model, the traditional logistic model will hereafter be called the static logistic model.

Dynamic Diffusion Models

Static diffusion models work best when the adoption process being modeled satisfies the assumptions (A1)–(A6) listed above, and when the inflection point for the adoption trend occurs at the same point as the inflection point for the functional forms listed above. For many applications, however, static diffusion models are open to two objections. First, in many cases there will be no rationale *ex ante* for assuming that diffusion follows a particular trend. Second, the assumption of a fixed ceiling on the adopting population is unrealistic in most economic contexts. For example, the potential number of adopters of a biological innovation will vary depending upon the availability of the innovation,

which itself is a result of the profit-maximizing efforts of firms.

Models are needed that allow more flexibility with regard to the inflection and symmetry points (Mahajan and Peterson 1985, Knudson). Dynamic models allow the determinants of diffusion to change every time period, and, hence, may more accurately measure the rate of adoption than a static model. For example, as the real price of an innovation decreases and stabilizes, an innovation becomes more attractive and is adopted more rapidly. A dynamic model could capture this change; a static model could not.

In addition, as a result of its flexible form, dynamic models can include more variables that affect diffusion and therefore measure more directly these factors' impact. For instance, the impact of such factors as prices or profit can be included in the diffusion model. Conceptually, then, a diffusion trend becomes an envelope of individual, distinct diffusion trends that a set of distinct variables define in each time period (Chow; Mahajan and Peterson 1978, 1985; Metcalfe and Gibbons; Stoneman).

Studies by Mahajan and Peterson (1978) and by Metcalfe and Gibbons were used to develop such a dynamic model. In particular, the Mahajan and Peterson study established an approach for modifying static models. They began by relaxing assumption (A2), which states that N^M is fixed and finite, claiming that (A2) is inconsistent with theory and practice. To make N^M dynamic, Mahajan and Peterson defined N^M as a function $f(s(t))$, where $s(t)$ is a vector of "(potentially) all relevant exogenous and endogenous factors, both controllable and uncontrollable, affecting $N^M(t)$ " (p. 1590). How well $f(s(t))$ represents $N^M(t)$ depends on the accuracy in estimating $s(t)$ and the closeness of $s(t)$ or $f(s(t))$ in measuring $N^M(t)$. Hence, by redefining $s(t)$ or $f(s(t))$, this approach can be tailored to measure the diffusion of distinctly different innovations.

Metcalfe and Gibbons relaxed assumptions (A2)–(A4) to build a dynamic model that is "based upon the simultaneous development of market demand and the accumulation of productive capacity" (p. 5). They take a static logistic model and make $N^M(t)$ a function of a simple market demand equation, $c - ap(t)$, where $p(t)$ is prices paid by the consumer at time t . Their $p(t)$ is determined endogenously within an industry; hence, it represents the equilibrium price (reflecting the growth rate capacity and profit rate of a firm). Their model takes the final form;

³ A Gompertz model takes the form, $dN(t)/dt = bN(t) [\log N^M - \log N(t)]$, where b , and $N(t)$ and N^M are as defined in the text. The following is a proof that the Gompertz model has a maximum diffusion rate when 37% of the potential adopters adopt and is asymmetric.

Let N be expressed as a fraction of N^M , so $dN(t)/dt = bN(t) (\log N^M - \log N(t))$ becomes $(dN(t)/dt) (1/N^M) = b(N(t)/N^M) (\log(N^M/N^M) - \log(N(t)/N^M))$. Let $F(t) = N(t)/N^M$, and ignore the subscript t for convenience; $(dN(t)/dt) (1/N^M)$ becomes $dF/dt = bF(\log 1 - \log F) = bF(\log(1/F))$.

To find the maximum growth rate, F^M , differentiate with respect to F ; $(dF/dt)/dF = b \log(1/F) - bF^M(1/F^M) = 0$; rearranging, $b \log(1/F^M) = b \log(1/F^M) = 1$ or $F^M = 0.37$. The maximum diffusion rate occurs when 37% of the potential adopters have adopted and is skewed to the left, making the diffusion trend asymmetric.

$$(3) \quad dN(t)/dt = g(t) [N^M(t) - N(t)],$$

where $g(t)$ is a function of technology, the natural rate of diffusion, and the capacity for a firm to invest in research and development.

The approach utilized by Metcalfe and Gibbons relaxes many of the basic assumptions of the diffusion model listed in the preceding section. By allowing the adoption ceiling to be a function of time (as well as technology and the parameters of equilibrium demand and supply), the assumption of a fixed adoption ceiling (A2) is relaxed. All three components $g(t)$ listed above may change every time period; hence (A3) (the assumption that the diffusion coefficient is fixed) is relaxed. (A4) is relaxed as the model allows directly for improvements in the innovation and for improvements in the means of producing the innovation. (For further details of model (3); see Metcalfe and Gibbons and Metcalfe.)

Modeling the Diffusion of Semi-Dwarf Wheat

Metcalfe and Gibbons present their model as a means of incorporating the full effects of the invention side in the diffusion process. Unfortunately, the cost data required for the profit rate equation are virtually impossible to obtain. Similarly, revenue for a research project is difficult to obtain, and as a result one cannot estimate marginal revenue to approximate marginal cost. Furthermore, not many proxies for research costs are available. The Metcalfe and Gibbons model, while theoretically appealing, is difficult to estimate empirically.

A model overcoming these data limitations was developed to estimate the diffusion of semi-dwarf wheat varieties (SDWV) across the U.S. Let the maximum number of adopters be a function of a wheat supply function, $N^M(t) = f(s(t)) = y(t)$, where y is the supply of wheat from semi-dwarf wheat seeds that farmers produce in time t . More specifically,

$$(4) \quad y(t) = f(pr(t), pp(t), pf(t)) \\ = c + a^1 pr(t-1) + a^2 pp(t-1) \\ + a^3 pf(t-1),$$

where $pr(t-1)$ is the price farmers receive for a bushel of grain in year $t-1$, $pp(t-1)$ is the price paid for SDWV seed in time $t-1$, and $pf(t-1)$ is the price paid for fertilizer in time $t-1$.

Two factors stand out in this functional form (3). First, the price variables are lagged one year.

Because a substantial lag exists between the time when production decisions are made to when production ends, price variables are often lagged. In this case, the hypothesis that a producer's expectation of prices is based on relatively recent experience is used (Tomek and Robinson). Second, the price variables are not deflated by a common deflator. Instead, the price variable that would have been the deflector is represented as a separate variable. In this case, the effect of fertilizer prices is measured.

Measuring the impact of fertilizer prices as an independent variable makes sense for two reasons. First, for the innovation studied here (SDWV), high yields were obtained through the use of heavier fertilizer application. Therefore, the use of fertilizer as a deflator may bias the regression results (Tomek and Robinson). Second, because fertilizer prices fluctuated greatly in the 1970s, separating prices received and other input prices from fertilizer prices allows for more accurate measurements of the impact of these variables on supply (Meilke).

The main difference between this model of diffusion and that of Metcalfe and Gibbons is that prices are now exogenous. However, because the supply function depends on factors that affect a farmer's decision to adopt, a supply function still connects the stages of research and development and diffusion/adoption. For example, suppose high fertilizer prices deter the adoption of SDWV. A firm may use this information to develop SDWVs that are less dependent on fertilizer. Furthermore, as prices favor a particular production process, such as SDWV and increased fertilizer use, farm producers may use these inputs to utilize a profitable opportunity (Schumpeter). Work by Peterson, and Timmer and Falcon show for various commodities that as the real price of the agricultural product increases, its supply also increases. Hence, a supply function similar to that found in equation (4) also captures the ceiling of SDWV adoption.⁴

Substituting (4) for N^M in equation (1) yields

$$(5) \quad dN(t)/dt = bN(t) (c + a^1 pr(t-1) \\ + a^2 pp(t-1) + a^3 pf(t-1) - N(t)),$$

where $dN(t)/dt$ is the rate of diffusion in time t , $N(t)$ is the number of adopters in time t , b is the natural rate of adoption, and $c, a^1, a^2, a^3, pr(t$

⁴ The demand elasticity is assumed not equal to zero since in that case firms would not respond to the lowered price of the innovation. Therefore, technological change would have no effect on the firm.

-1), $pp(t-1)$, and $pf(t-1)$ are defined above. In equation (5), as in the Mahajan and Peterson model, the maximum number of adopters does not remain fixed over time; therefore, (A2) is relaxed. Similar to the Metcalfe and Gibbons model, the innovation is allowed to change over the diffusion process through the supply function found in equation (4); hence, (A4) is relaxed.

Estimating the Diffusion of SDWV

The parameters for the static logistic model (2) and the dynamic logistic model (5) are estimated by rewriting each equation in its discrete analogue form and then applying generalized least squares (GLS) (Mahajan and Peterson 1985, Bass, Chow, Bayer and Melone, White).⁵ In terms of its discrete analogue form, $dN(t)/dt = N(t) - N(t-1)$. Substituting the discrete analogue form into the static logistic model (2), and multiplying the right-hand side of (2) out, (2) becomes

$$(6) \quad N(t) - N(t-1) = (bN^M)N(t) - bN(t)^2,$$

where $bN^M = A$, $-b = E$, and $N(t)$ and $N(t)^2$ are the same as they were [in (2)]. Equation (6) becomes by substitution,

$$(7) \quad N(t) - N(t-1) = AN(t) + EN(t)^2.$$

Doing the same for the dynamic logistic model, equation (5) becomes

$$(8) \quad N(t) - N(t-1) = (bc)N(t) + (ba^1)N(t)pr(t-1) + (ba^2)N(t)pp(t-1) + (ba^3)N(t)pf(t-1) - (b)N(t)^2.$$

Let $A = bc$, $B = ba^1$, $C = ba^2$, $D = ba^3$, and $E = -b$, and substitute, A , B , C , D , and E for these terms in (8). Now, (8) becomes

$$(9) \quad N(t) - N(t-1) = AN(t) + BN(t)pr(t-1) + CN(t)pp(t-1) + DN(t)pf(t-1) + EN(t)^2.$$

One can now apply GLS to both equations (7) and (9).

For both models, the A coefficient is expected to be positive and the E coefficient negative. The greater the increase in the number of adopters, $N(t)$, between two time periods, the greater the

diffusion rate, $N(t) - N(t-1)$. However, as the number of adopters increases, the number of potential adopters decreases. Adoption continues to increase but at a decreasing rate.

For the dynamic logistic model, a positive B coefficient is expected and negative C and D coefficients are expected. Producers supply more of a commodity as its real market price increases. Hence, as prices increase, so does adoption and the diffusion rate. However, as an input price decreases, assuming everything else remains constant, the profitability of using that input increases, causing its adoption to increase.

Variables Used

Both the static and dynamic logistic models use the variable $N(t)$. In addition, the dynamic model also uses the variables $pr(t-1)$, $pp(t-1)$, and $pf(t-1)$. $N(t)$ is measured by the percentage of total wheat land planted to SDWV's. This measure is a flexible variable, capable of capturing disadoption trends. This allows one to take advantage of relaxing assumption (A5).

An alternative measure of $N(t)$ is the area of land planted with SDWV's. One advantage of using the relative measure is to maintain consistency with other studies that measured the diffusion of a new crop variety. Griliches (1957) and Dixon used percentage of corn land planted to hybrid corn to measure hybrid corn adoption. A second justification for using the relative measure is that this study addresses the extent to which wheat farmers use SDWVs as opposed to traditional varieties. Because the only commercial alternative for wheat farmers is either the traditional or the SDW option, the relative proportion of wheat land going to SDW allows one to track the adoption of SDWV over traditional varieties within the adoption population of interest, i.e., wheat farmers. By contrast, using the absolute measure gives no insight into the adopting behavior of wheat farmers because increases in the total land planted with SDWVs need not reflect displacement of the more traditional varieties.⁶

Data on the percent of SDWV acreage relative to total wheat acreage are collected from a

⁵ The Goldfeld-Quandt test for heteroskedasticity was statistically significant and was corrected following the methodology of White.

⁶ As a check, the model was rerun using the absolute acreage measure. The results were confusing. For example, the coefficients for $N(t)$ imply that the adoption occurred first in regions where the SDWV technology appeared last and conflicts with evidence (such as the data from the Wheat Marketing Survey) that shows otherwise. This result may reflect the erratic wheat acreages during the 1960s and 1970s.

wheat marketing survey by U.S. Department of Agriculture (USDA) every five years. These data are aggregated so the unit of analysis is on a per state basis. The survey is run across forty-two states. Data on SDWV acreage allotment are available for forty-one of these states. Florida is excluded because of lack of data for many years on their wheat plantings.

The survey years for which SDWV data are available are (a) 1959, 1964, 1969, 1974, 1979, and 1984 for Idaho, Montana, Nevada, Oregon, and Washington; and (b) 1964, 1969, 1974, 1979, and 1984 for the remaining thirty-six states.

The three price variables in the model (Pr , Pp , and Pf) are measured as follows: Pr , expected wheat prices received, is set equal to the average annual price received per bushel of wheat. ($N(t - 1)$ refers to the preceding wheat survey year. However, the price variables are lagged only one year.) The price received "allows for unredeemed loans and government purchases values at the average loan and purchase rate" (USDA ERS, p. 24). Expected prices paid for seed, Pp , equals the average annual price paid for seed. The USDA publishes seasonal average wheat price data. Finally, Pf , expected prices paid for fertilizer, is measured by total plant nutrient expenditures (million dollars) ($Pf * Qf$, where Pf is price of plant nutrients and Qf is quantity of plant nutrients) divided by the quantity of plant nutrients consumed on the national level (1,000 tons), i.e., $Pf * Qf / Qf = Pf$. This price accounts for technological improvements in fertilizer. As improvements occur, a unit of fertilizer will produce more nutrients, hence, reducing the real price of fertilizer. Because prices using plant nutrients are adjusted for quality and USDA fertilizer prices are not, USDA fertilizer prices are biased upwards. Therefore, this study used this measure ($Pf * Qf / Pf$) of fertilizer prices.

Table 2. Characteristics for States within Each Group

Group	Wheat Market Class

G2	Hard Red Spring
G3	Hard Red Winter
G4	Soft Red Winter
G5	Soft Red Winter

Cross-Sectional and Time-Series Data

Because of the lack of time-series data on a per state basis and the abundance of cross-sectional data, equations (7) and (9) were estimated using cross-sectional and time-series data. The level of analysis using cross-sectional and time-series data is the individual as opposed to a time point. For this study, the movement of SDWV adoption in one region will be described relative to its movement in another region. The advantage is that all adopters' behavior will be directly comparable.

Equations (7) and (9) must be reformulated for use in cross-sectional and time-series analysis using a slope dummy variable framework. The forty-one states are divided into five groups based on their location and similarity in wheat and growing conditions. See tables 1 and 2 for a listing of the groups and their characteristics.

A base group was selected to provide a means of comparing SDWV diffusion rates between regions. The other groups were formulated using dummy variables. The model measures the diffusion of SDWV for the base group and how the other groups differ directly from the base group. Therefore, the base group must be different enough from the rest of the groups so that statistical differences between groups can be picked up. In this study, a good base group would

Table 1. State Groups

Group One (G1) (West)	Group Two (G2) (Upper Midwest)	Group Three (G3) (Plains)	Group Four (G4) (South)	Group Five (G5) (East)
Arizona	Michigan	Colorado	Alabama	Delaware
California	Minnesota	Illinois	Arkansas	Indiana

New Mexico	North Dakota	Missouri	Mississippi	New Jersey
Oregon	South Dakota	Nebraska	North Carolina	Ohio
Utah	Wisconsin	Oklahoma	South Carolina	Pennsylvania
Washington		Texas	Tennessee	Virginia
		Wyoming		West Virginia

be one where either high or low SDWV diffusion occurred. Since SDWV diffusion was most rapid in Group 1, the West, this region was chosen as the base group.⁷

Results and Discussion

The results of the static logistic model (7) and the dynamic logistic model (9) are presented in tables 3 and 4, respectively. In both tables, the reported coefficients equal the coefficients from the base group plus the coefficient from the dummy variable for that particular variable in that region. The standard errors and *T*-statistics, however, are for the test that the coefficient for that region is significantly different from the coefficient for the base region (the West). Only the *T*-statistic for the West region is appropriate for determining whether the coefficient is significantly different from zero.

Overall, the dynamic model provides a better fit to the data than the static model. Adjusting

for additional explanatory variables in the dynamic model increased the *R*-squared measure from 0.45 to 0.67. In addition, the pattern of diffusion in the two models is quite similar. Considering the coefficients on *N* and *N*², both models show similar patterns of signs for the coefficients. In the West and Upper Midwest, increases in the number of cumulative adopters leads to increases in the diffusion rate, although the increases occur at a diminishing rate for larger numbers of cumulative adopters. This deceleration is not observed in any of the other three regions, where both the static and the dynamic diffusion models show a positive coefficient for the *N* and *N*² coefficients. However, these positive coefficients for *N*² for the Plains, the South, and the East may indicate that SDWV have not yet fully diffused in these regions.

Analysis of the value of wheat relative to total farm production in each region substantiates the patterns revealed in the *N* and *N*² coefficients. As noted in Griliches (1958), the higher the total value of a crop, the faster the acceptance rate. Wheat has the highest value in the West, the upper Midwest, and the Plains. The South and the East lag behind. This relationship suggests that adoption of SDWVs has progressed most fully in the West and upper Midwest, and less so in the other regions. If true, this result suggests that future empirical analysis of the diffusion of SDWVs in the Plains, South, and East should yield the expected negative coefficient *N*², as the regions become saturated and increases in land devoted to SDWVs decelerates.

⁷ Each of the groups act as one unit. The states within each group have fairly homogenous SDWV diffusion rates. Some states within a group may lag behind. But, because of the spillover effect, close locality, and similar market classes of wheat grown, it is assumed SDWV technology was similarly transferred among these states.

In order to check the homogeneity among states within each group, each group was run by itself in a cross-section and time-series logistic framework. The base states were Oregon, New York, Oklahoma, South Carolina, and Virginia. With the exception of Kansas, Texas, Indiana, Pennsylvania, North Carolina, and Mississippi, the states, within their respective groups, were not significantly different from the base group. Other groupings were also tested, but only this division gave strong results within and between regions.

¹ States and characteristics of each group are found in tables 1 and 2.

The price coefficients from the dynamic model are less enlightening. In particular, the signs on the coefficients for the prices received (*Pr*) and prices paid for seed (*Pp*) do not follow any clear pattern. There are four potential explanations for this failure.⁸ First, farmers may not be price responsive, at least to these two variables. Second, these price variables may have a significant effect but not in a way that the model estimated here can uncover. For example, prices paid for seed may interact with another variable

(such as farm income), and through this interactive effect may significantly affect adoption. Finally, coefficient estimates may be confused because of the lack of variation on the *Pr* and *Pp* variables. For example, this lack of variation may be attributed in the former case to government programs maintaining artificially high prices for wheat. Fourth, the estimated model suffers from collinearity, since the price variables are all multiplied by *N*, which is also an independent variable in the model.⁹

⁸ The dynamic model was run using long-term prices for all three variables (measured by a five-year lagged average). Long-term prices not only gave signs that followed less of a pattern than those obtained in the short-run prices case, but also had lower *t*-statistics. Thus, it is not the use of short-run output prices per se that is responsible for the pattern of coefficients on the price variables. Theoretical justification for the use of one-year lagged prices is presented in Tomek and Robinson.

⁹ The correlations between *N* and *NPr* and between *N* and *NPp* were roughly 0.9. The correlation between *N* and *NPf* was slightly less. Although there are techniques to correct for near multicollinearity, such as bayesian mixed estimation and adding data, neither were feasible here (because of the lack of a second data set). Results from models with multicollinearity are unbiased, although inefficient. This implies that multicollinearity cannot account for the switched signs on some of the price variables, although it may account for the small *t*-statistics.

On the other hand, fertilizer prices (P_f) have influenced the diffusion of SDWV, particularly in the West, the Upper Midwest, and the Plains (the three high value-of-wheat regions). For these three regions, the sign is correct, indicating that as the price of this input decreases, farmers purchased more SDWV seed. It is not surprising that fertilizer prices have a significant impact on SDWV diffusion. The improved yield capacity of SDWV over standard tall varieties was largely the result of its ability to withstand heavier heads brought about by increased fertilizer applications.

Fertilizer prices appear less important in explaining the behavior of the late-adopting regions of the South and the East. This result is consistent with Cochrane's treadmill theory (Cochrane 1958, 1986). According to Cochrane, as diffusion proceeds, the role of prices may diminish if the higher production dampens prices. While the initial increase in production because of the adoption of a new technology may not be enough to increase total supply, early adopters reap the benefits of new technologies through receiving old prices and increasing output per unit of input. However, middle and late adopters cause supply to increase appreciably. As a result, middle and late adopters do not benefit from an increase in the total value product over an increase in total costs.

Concluding Comments

This paper has presented a method by which diffusion models can incorporate dynamic factors such as changes in the maximum number of adopters and in the technology and the possibility of disadoption. The approach allows the researcher to avoid the extreme data burdens (in particular, the necessity for cost data) that arise in other dynamic diffusion models. This method was used to estimate the diffusion of semi-dwarf wheat varieties (SDWVs) in the United States from 1959–84. Comparisons with results from a static diffusion model show that the dynamic model provides a better fit to the data as well as offering insights into the economic determinants of adoption.

The results of this paper also indicate the importance of including other innovations that affect the diffusion or development of the innovation being studied. The pattern of adoption of SDWV's was affected to a considerable extent by changes in fertilizer prices, which themselves resulted from technological innovations

in the fertilizer industry. Incorporating these complex relationships may be necessary in order to explain satisfactorily the patterns of adoption of technological innovations. For example, a firm trying to market herbicide resistant varieties must consider the price of herbicide and other inputs as well as the management skills needed to assure the prompt adoption of these new varieties. Policy analysts may need to consider how price affects the adoption of new agricultural practices, such as low input agricultural practices.

This point is pertinent to many agricultural process innovations being developed today. Due to the poor prices of the 1980s, and the current concern over the environment, many agricultural companies are marketing production packages instead of just one input. Hence, they need models, such as the one developed in this paper, that allow for the impact of another innovation.

A Bayesian Approach to Explaining Sequential Adoption of Components of a Technological Package

Howard D. Leathers and Melinda Smale

Agricultural innovations are often promoted as a package—a new seed variety, a recommended fertilizer application, and other recommended cultivation practices. Nevertheless, many farmers adopt pieces of the package rather than the whole, in a sequential fashion. This paper presents a behavioral model which explains sequential adoption as a consequence of learning by adopting farmers. In order to learn more about the entire technological package, the farmer may adopt a part of the package. The model is shown to be consistent with observed patterns of sequential adoption.

Key words: Bayesian learning, diffusion of technology, technology adoption.

In U.S. agriculture before 1950, the “Green Revolution” of the 1960s, and in other regions since then, agricultural research institutions have developed and promoted innovations as packages of farming practices consisting of a seed variety, fertilizer application, and other cultivation techniques (Moseman, Ryan and Subrahmanyam, Lele and Goldsmith). Empirical evidence suggests, however, that farmers often adopt pieces of the package rather than the whole, in a sequence or “stepwise” fashion (Byerlee and Hesse de Polanco, Mann, Ryan and Subrahmanyam).

Economists working with agricultural research institutions have argued that sequential adoption may reflect rational choice by farmers, but the reasons for the decision are not clearly understood. Byerlee and Hesse de Polanco state that “because of capital scarcity and risk considerations, farmers are rarely in a position to adopt complete packages” (p. 519). Even when provided with advantageous credit and input delivery arrangements, “farmers . . . experiment with recommendations, often adopting them in stages rather than as a complete package” (Cummings, p. 24). In their review of literature

on agricultural innovations in developing countries, Feder, Just, and Zilberman conclude that “further work is needed to understand any order and regularity in such chain processes” (p. 288).

Explanations for sequential adoption have not yet been framed in a behavioral model, and most behavioral models have investigated the factors that affect the adoption of a single component or a package, rather than the pattern of component adoption (O’Mara; Hiebert; Lindner, Fischer, and Pardey; Lindner; Lindner and Fischer). Feder’s model is one of the first to explore how the interrelationship between recommended inputs influences a farmer’s adoption decision.

In this paper, we offer a Bayesian model that explains sequential adoption even when farmers are risk neutral and unconstrained in their expenditures. The model depicts a farmer who is uncertain whether the information she/he receives about a recommended innovation accurately describes her/his own prospects. Uncertainty is reduced but may not be resolved through experience. The model demonstrates that in order to learn more about the innovation, the farmer may choose to adopt a component rather than the package, even when the package is more profitable.

Empirical evidence of sequential adoption is reviewed in the next section, and several plausible explanations for sequential adoption are explored. Following the Cummings suggestion that farmers adopt components to “experiment”

Howard D. Leathers is an assistant professor, and Melinda Smale is a graduate student at the University of Maryland.

This research was funded in part by a grant from Centro Internacional de Mejoramiento de Maíz y Trigo. The views expressed are those of the authors.

Many helpful comments were received from Paul Heisey and Derek Byerlee. Remaining errors are those of the authors.

with recommendations, a Bayesian model of learning is presented which can explain sequential adoption. A simplified version of the model illustrates the main points and the implications of the model are discussed.

Evidence on and Explanations of Sequential Adoption

In a variety of settings, new technologies have been introduced as packages of innovations (Moseman, Lele and Goldsmith). Typically, the technological package is developed by interdisciplinary teams of plant breeders, agronomists, and soil scientists that seek to maximize yield by capturing the biological and chemical interactions among its components. In a rural environment where information dissemination costs are high, the package represents a "clear model to strive for in the longer run" and rewards early adopters with "dramatic yield increases to motivate others" (Mann, p. 75). Technological packages are designed to exploit interactions among the components. For example, yield increases from adoption of new seed may be further improved by applying appropriate levels of fertilizer and irrigation or modifying plant density.

The question to be addressed is: Since these interactions exist, why do farmers adopt pieces of the package at first (failing to take advantage of the interactions), and only later adopt the entire package? Empirical evidence of sequential adoption has been found in Turkey, Mexico, India, Pakistan, and Zimbabwe. (See Mann, Byerlee and Hesse de Polanco, Husain, Lowdermilk, Heisey et al., CIMMYT, Rohrbach, Ryan and Subrahmanyam). The empirical evidence shows the following: (a) For the most part, farmers choose to adopt inputs sequentially, adopting initially only a part of the package and subsequently adding components over time. (b) In some instances, farmers adopt a component and subsequently revert to the traditional agricultural practices. (c) Adoption patterns vary by agroecological zone (i.e., in one part of Pakistan, a new seed is typically adopted first; while in a different part of Pakistan, fertilizer is adopted first). (d) Adoption patterns vary within agroecological zones, among farmers facing similar markets and institutions.

The authors cited above have identified profitability, riskiness, uncertainty, lumpiness of investment, and institutional constraints as pos-

sible explanations for sequential adoption. A simple economic explanation of adoption behavior would suggest that a farmer will choose the most profitable technology and will continue to use that technology as long as relative prices remain unchanged. This simple model suggests: (i) Farmers operating under identical conditions will choose identical technological combinations, contradicting observation (d) above. (ii) As economic conditions change, farmers will switch from a component to the whole package in some cases, and from the whole package to a component in other cases, contradicting observation (a).

Ryan and Subrahmanyam postulated that "each part of the package might be looked upon by farmers as a less risky activity than the complete package in terms of what the farmer could lose if crop failure results" (p. A101). In other words, although expected profits may be maximized by adopting the package, expected utility may be maximized by adopting a component. This explains why a farmer chooses a part rather than the package, but not how the choice evolves over successive seasons. To explain adoption sequences, the approach requires assumptions about systematic changes in risk parameters or underlying preferences.

Ryan and Subrahmanyam found that the additional profits earned per unit of expenditures on a practice requiring "minimal change" was at least as great as the profit rate associated with the more complex, expensive packages. They argue that sequential adoption of components is a rational choice for a farmer with limited cash. As cash is accumulated from producing with the parts of the package, farmers will add components until the entire package has been adopted. This explanation suggests that a constrained farmer will adopt the choice which has the highest profit per dollar of expense, while an unconstrained farmer will adopt the choice which has highest profits.

Thus, a credit constraint can explain why a farmer may adopt a component even when the package is more profitable. However, the explanation exhibits two weaknesses. First, the model predicts that within a region, all credit-constrained farmers facing the same set of relative prices would adopt technological components in the same sequence. Second, when the input package displays "profit rate complementarity" (as defined by Ryan and Subrahmanyam, when the profit per dollar of expense is higher for the package than for any component), a credit constraint cannot explain why the farmer chooses

part rather than all of the package.¹ When profit rate complementarity exists, the credit-constrained farmer will adopt the whole package but perhaps on a smaller part of the land. If the additional assumption is added that the farmer must purchase the package in large, indivisible units, the credit constraint model can predict adoption of a part even when the package has the highest profit to cost ratio. By contrast, in the Mexican, Pakistani, and Zimbabwean cases cited above, the package inputs were described as highly divisible, variable inputs.

A Bayesian Approach to Technology Adoption

None of the above hypotheses is a consistent explanation of observed sequential adoption behavior. Cummings's observation that farmers experiment with recommendations suggests a learning model as a possible explanation. Many economists have used Bayesian approaches to explain aspects of technology adoption (O'Mara; Jensen; Hiebert; Stoneman; Feder; various papers by Lindner and others; Grossman, Kihlstrom, and Mirman).

Of special interest is Cyert and deGroot's model of financial decisions of a firm. In the model, the firm is considering investment in a large, fixed asset, and personnel may understate certain perceived risks associated with the project in order to obtain funding. Managers may choose to divide the investment into parts or modules that enable them to invest sequentially according to revised profitability expectations. Their decision is complicated by the fact that higher investment levels may provide more accurate information while increasing the investment risks. Cyert and DeGroot also show that it may be optimal for managers to invest partially (in some modules) if they can invest sequentially, even when the optimal investment would be zero in nonsequential conditions.

The notion that a choice will generate not only income but also information forms the basis of a behavioral model in which sequential adoption of new technology is a rational response. A general form of the model is presented in this section, followed by a simplified version illustrating the main points in the next section.

A producer will be in business T periods. Each

period, the producer chooses an action d_t from the decision set D_t . The choice each period generates stochastic income $y_t(d_t, \epsilon_t)$, where ϵ_t is the realization of a random variable ϵ with probability density function, f . The probability density function is not known with certainty but is known up to a vector θ . The decision maker has beliefs about what values θ can take; these beliefs are characterized by a probability density function $g_t(\theta; I_t)$ which is a function of the information possessed by the decision maker in period t (I_t). The information about θ includes the decision maker's past observations of d and y , as well as any other information i available at time t : $I_t = I_t(d_{\tau < t}, y_{\tau < t}, i_t)$. The probability distribution g_t is derived by a Bayesian update of the prior distribution, g_{t-1} , using the information set I_t .

The decision maker maximizes the present value of subjective expected utility (using discounting factor ϕ):

$$\text{Max}_{d_0, \dots, d_T} \sum_{t=0}^T \phi^t EU_t,$$

where $EU_t = \iint U(y_t(d_t, \epsilon))f(\epsilon, \theta)g(\theta, I_t) d\epsilon d\theta$. The problem is solved by backward induction, and the solution is the sequence $\{d_t^*\}$, for $t = 0 \dots T$.

The decision in any period is

$$\text{Max}_{d_0} E_t U_t(y_t(d_t)) + \sum_{i=t+1}^T E_t \text{Max}_{d_1, \dots, d_T} E_i U_i(I_i(d_i)),$$

where E_t denotes the expectation in period t and U_i denotes the utility in period i . This representation decomposes the effect of each period's choice into a direct effect influencing income in that period y_t , and the indirect effect of influencing the information available in future periods. The "full information optimum" is the choice d_t^{fi} which maximizes $\int U(y_t(d_t, \epsilon))f(\epsilon, \theta^{\text{fi}}) d\epsilon$, where θ^{fi} is the true (full information) value of θ . If full information becomes available at period \bar{t} , then for all $t \geq \bar{t}$, $g(\theta^{\text{fi}}) = 1$, $g(\theta \neq \theta^{\text{fi}}) = 0$, the informational content of any choice d_t is zero and $d_t^* = d_t^{\text{fi}}$. However, for $t < \bar{t}$, d_t^* will differ from d_t^{fi} whenever the sacrifice in expected utility in the current period is more than compensated by higher expected utility in future periods obtained with the better information.

This model is intentionally a very general model of producer decisions in the presence of risk and incomplete information. Sequential adoption of parts of a new technology is only one part of the decision-making process. Tech-

¹ Profit rate complementarity implies profit complementarity as defined by Feder, when profits of the package exceed profits of any component.

nology adoption consists of three distinct decisions within one optimization problem: a discrete choice of technological package, a continuous choice of land allocation between the new and traditional technology, and a choice of input levels. In the context of the above model, the choice set D_t may consist of elements which specify the components of new technology, the extent of new versus traditional agricultural techniques, and the intensity of adoption. For example, one element of D_t might be "use traditional growing techniques on two hectares, a new seed variety at the recommended seeding rate on one hectare, and the new seed variety at 80% of the recommended seeding rate on two hectares.

This paper focuses on the first of these three decisions: which components of the new technology to adopt. It is clear how this model offers an explanation for observed sequential adoption behavior. If the package is the combination of components which performs best among all possible combinations of new techniques, d_t^f will include the recommended package (perhaps along with traditional growing practices).

However, in periods $t \leq \bar{t}$, if the information gleaned from adopting a part of the package is a better bargain than information gleaned from adopting the package as a whole, d_t^f may include some component or components of the package, rather than the entire package. Certainly, if farmers can learn about the whole package by buying only a part of it, there will be an information incentive to buy the part rather than the whole.²

This model is consistent with all empirically observed facts. For the most part, individuals will move from the part to the whole package as they gain better information about the package. Occasionally, individuals will learn that the package is not appropriate for them. Normal adoption patterns will differ from region to region because of differences in direct effects and informational effects. Adoption patterns will differ from individual to individual within a region because of differences in the Bayesian priors of individuals in period zero. All of these points

are illustrated in the simple illustration presented below.

A Simple Illustration

The general model of learning relies on two basic conditions: the farmer is uncertain about the net returns associated with adopting a new technological package, and the uncertainty may not be resolved by adopting the package. The farmer operates for two production periods ($T = 2$), and decides in each period whether to adopt a new seed variety, a commercial fertilizer, or both. Thus the decision set contains three elements: $D_t = \{S, F, B\}$, where S represents the adoption of seed, F the adoption of fertilizer, and B the adoption of both. The decision is influenced by information that an extension agent provides about the effectiveness of the techniques. The extension agent claims that the additional costs and returns associated with adoption of the new techniques are those shown in table 1. R_S, R_F, R_B are expected revenues from the possible choices, C_S, C_F, C_B are costs of the choices, α, β, γ are probabilities, and s, f , and b are constants.

The farmer is not certain that these figures correctly indicate how new techniques will perform on his/her fields.³ If the extension agent's report is not valid for his/her farm, the farmer believes that additional costs and returns are shown in table 2.

Both of the basic conditions of the model are met. First, the farmer is uncertain about which of the two tables is appropriate to his/her farm. Second, because the "low revenue" when the report is valid is identical to the "high revenue" when the report is not valid, farming experience will not always eliminate uncertainty. If this ambiguous level of revenues is observed, the farmer cannot distinguish whether it expresses a high revenue and an invalid report or low revenue and a valid report.

Superscripts 1 and 2 refer to periods, and subscripts S, F , and B denote the adoption of seed only, fertilizer only, or both seed and fertilizer. Expected profits earned in a period by the farmer, conditional on a valid extension report, are de-

² The decision of how extensively to apply the new (experimental) technique will be influenced by the farmer's subjective judgment about its ultimate applicability. If the farmer is doubtful about whether the new technology is an improvement on traditional practices, he/she may try the new technique on only a small portion of land. This will be especially true if the farmer can learn as much from trying the new technique on a small versus a big plot.

³ A farmer's experience may differ from extension claims because of differences in objectives, agroecological conditions, or related technology (Herd). Research institutions work with "groups of farmers for whom the frequency distributions of expected yield increments will not be very compact due to agroclimatic variability" (Perrin and Winklemann, p. 892).

Table 1. Additional per Hectare Costs and Returns of New Techniques If Extension Report Is Valid

Technique	Low Revenue	Probability of Low Revenue	High Revenue	Probability of High Revenue	Expected Revenue	Cost
Seed	$R_s - s/(1 - \alpha)$	$(1 - \alpha)$	$R_s + s/\alpha$	α	R_s	C_s
Fertilizer	$R_f - f/(1 - \beta)$	$(1 - \beta)$	$R_f + f/\beta$	β	R_f	C_f
Both	$R_b - b/(1 - \gamma)$	$(1 - \gamma)$	$R_b + b/\gamma$	γ	R_b	C_b

noted by π (e.g., $\pi_B = R_B - C_B$). Expected profits conditional on an invalid extension report are denoted by μ (e.g., $\mu_B = (1 - \gamma)R_B - b - C_B$). The farmer believes that the report is valid with probability δ . The farmer's subjective unconditional expected profit is denoted by ψ (e.g., $\psi_B = \delta\pi_B + (1 - \delta)\mu_B$).

In this example, farmers are assumed risk neutral. In addition, certain relationships between inputs are also assumed in constructing the model, and are contained in the expressions:

$$(1) \quad \pi_B > \pi_S > 0, \quad \pi_B > \pi_F > 0;$$

$$(2) \quad \mu_S < \mu_B < 0, \quad \mu_F < \mu_B < 0.$$

The first assumption formalizes the notion that the components of the technological package are profit complementary and implies that adopting either part of the package is preferred to the traditional technique when the extension report is valid.⁴ The second assumption states that the components are complementary even when the extension report is invalid and implies that under those conditions the (risk-neutral) farmer prefers current techniques. The two assumptions, combined, indicate that the farmer's unconditional expected profits are higher with the package than with any part, or

$$(3) \quad \psi_B > \psi_s \text{ and } \psi_B > \psi_F.$$

⁴ Unlike the credit constraint explanation of sequential adoption, we make no assumptions about profit complementarity: $\Pi_B/C_B > \Pi_s/C_s > \Pi_F/C_F$ is permitted, but not required, by this formulation.

For ease of exposition, δ is defined to range in magnitude close enough to 1 that $\psi_B > 0$. The inequality can be reversed without affecting the fundamental arguments generated by the model.

The farmer operates for two periods, using experience gained in the first period to guide his/her choice in the second by updating, according to Bayes's rule, the subjective judgment about the value of δ . When only seed is adopted in the first period, the farmer faces one of three possible outcomes. An outcome of $(R_s + s/\alpha)$ proves that the extension report is valid, and the farmer updates the first-period subjective probability (δ^1) to $[\delta^2 = 1]$ in the second period. An outcome of zero revenue confirms that the extension agent is wrong, and the farmer's updated subjective probability is $[\delta^2 = 0]$. In either of the two outcomes, the first-period experiment eliminates uncertainty in the second period.

By contrast, an outcome of $R_s - [s/(1 - \alpha)]$ is ambiguous: the farmer cannot determine whether the outcome occurred because the extension report is invalid, and the technology performed well; or because the report is valid, but the technology performed poorly. When first-period choice results in this ambiguous level of revenue, the farmer's updated subjective probability is $\delta^2 = [\delta^1(1 - \alpha)]/[(1 - \alpha)(\delta^1 + 1 - 0\delta^1)] = \delta^1$. In other words, the updated subjective probability is the same as the prior. Analogous alternative outcomes exist for a technology choice of fertilizer only or the package of both seed and fertilizer.

As the problem is formulated, the experience

Table 2. Additional per Hectare Costs and Returns of New Techniques If Extension Report Is Not Valid

Technique	Low Revenue	Probability of Low Revenue	High Revenue	Probability of High Revenue	Expected Revenue	Cost
Seed	0	α	$R_s - s/(1 - \alpha)$	$(1 - \alpha)$	$(1 - \alpha)R_s - s$	C_s
Fertilizer	0	β	$R_f - f/(1 - \beta)$	$(1 - \beta)$	$(1 - \beta)R_f - f$	C_f
Both	0	γ	$R_b - b/(1 - \gamma)$	$(1 - \gamma)$	$(1 - \gamma)R_b - b$	C_b

of the first period will completely eliminate uncertainty in two cases: when revenue greater than R_i (expected revenue when alternative i is chosen and the extension report is valid) is observed, the farmer knows that the extension report must be valid; when revenue of zero is observed, the farmer knows that the extension report must not be valid. The probability of attaining certainty through the first year's experience is α for farmers who adopt seed only, β for farmers who adopt fertilizer only, and γ for farmers who adopt both seed and fertilizer. The probabilities of observing the ambiguous, middle revenue are, respectively, $(1 - \alpha)$, $(1 - \beta)$, and $(1 - \gamma)$.

The crux of this example is that observing middle revenue does not inform the farmer about the validity of the extension report. If that ambiguous revenue occurs, the possibility remains that the second-period choice will be "wrong." In the second period, the farmer may choose to adopt the package although the extension report is invalid or, conversely, may not adopt even though the extension report is valid. The farmer's decision about production techniques in period one is, therefore, influenced not only by the profits expected in that period but also by the informational content of the choice. Better information acquired during the first period reduces the chance of making the wrong choice in the second period. The farmer recognizes that the second-period decision will be affected by the technology choice in the first period.

The risk-neutral farmer's objective is to choose the production technique in each period from a set that includes the traditional technique, seed only, fertilizer only, and the seed-fertilizer package, knowing that the decision in the second period is affected by the first-period choice. The choice is conditional on the farmer's subjective judgment about the probability that the extension report is valid. Some choices may be more informative about the package than others. Viewed from the first period, the farmer maximizes expected profits over the two periods and over the set of possible outcomes.

The farmer's problem is solved by backward induction. First, the optimal choice in the second period is identified conditional on the value of δ^2 . The parameter δ^2 takes one of three values. When $\delta^2 = 0$, the farmer is certain that the extension report is invalid; he/she chooses the traditional farming techniques in the second period, and earns zero additional profit per hectare. When $\delta^2 = 1$, the farmer is certain that the extension report is valid; he/she chooses the seed-

fertilizer package and earns additional expected profit of $\pi_B = R_B - C_B$. When $\delta^2 = \delta^1$, the farmer remains uncertain about the validity of the extension report, but he/she chooses the seed-fertilizer package because, by assumption, ψ_B is positive and larger than either ψ_S or ψ_F .

The expectation the farmer forms in the first period, E^1 , can then be expressed in terms of each of the possible first period choices. If the farmer chooses S in the first period, total expected profit viewed from period 1 is

$$\begin{aligned} E_S^1 &= \psi_S + \delta^1 \alpha \pi_B + \delta^1 (1 - \alpha) \pi_B \\ &\quad + (1 - \delta^1) \alpha \cdot 0 + (1 - \delta^1) (1 - \alpha) [\mu_B], \\ &= \psi_S + \delta^1 \pi_B + (1 - \delta^1) (1 - \alpha) [\mu_B]. \end{aligned}$$

If the farmer chooses F or B in the first period, expected profits are

$$\begin{aligned} E_F^1 &= \psi_F + \delta^1 \pi_B + (1 - \delta^1) (1 - \beta) [\mu_B] \\ &\quad \text{(for fertilizer only)} \\ E_B^1 &= \psi_B + \delta^1 \pi_B + (1 - \delta^1) (1 - \gamma) [\mu_B] \\ &\quad \text{(for the package).} \end{aligned}$$

The first term in each expression is expected return in the first period from using the indicated technique. The remaining terms show expected return in the second period conditional on the first-period choice.

The case of the farmer's decision to adopt only seed in the first period illustrates the problem. If the extension report is valid (with subjective probability δ^1), the farmer obtains revenue higher than R_i with a probability of α and observes the ambiguous revenue level with probability $(1 - \alpha)$. With either outcome, the farmer adopts the seed-fertilizer package in the second period, and earns expected additional profits of π_B . If the extension report is invalid [probability $(1 - \delta^1)$], the farmer earns zero revenue with probability α and the ambiguous revenue level with probability $(1 - \alpha)$ in the first period. When zero revenue occurs, the farmer reverts to the traditional technique in the second period and earns additional profits of zero. Observing middle revenue leads the farmer to adopt (mistakenly) the seed-fertilizer package in period 2 and to earn (negative) additional profits of μ_B .

Behavioral Implications

The above example demonstrates how the Bayesian model explains, without imposing institutional constraints or assuming risk aversion, why farmers may adopt components of a tech-

nological package sequentially even when the profitability of adopting the package is greater than that associated with the use of a component. In the first period, the farmer uses the technique which yields the highest expected return. A choice of seed only implies that $E_S^1 > E_B^1$, or

$$E_S^1 - E_B^1 = [\psi_S - \psi_B] + (1 - \delta^1)\mu_B[\gamma - \alpha] > 0.$$

The difference in the expectations consists of two terms.

The first term $[\psi_S - \psi_B]$ represents the difference in expected period one profits when the farmer chooses seed rather than the package. The term is negative by assumption; we are interested here in the case where the package is the "best" choice in the long run. The second term expresses the difference in expected costs caused by a mistaken choice in the second period. The probability associated with the mistake is $(1 - \alpha) - (1 - \gamma) = (\gamma - \alpha)$, and μ_B , which is negative by assumption, is the cost of choosing to adopt the package in the second period when the "correct" (highest expected profit) choice is the traditional technique. As the problem is depicted, a necessary condition for adoption of only seed in the first period is $\gamma < \alpha$, or that probability of earning high revenue with the package, when the extension report is valid, is less than the probability of earning high revenue with seed only. Because γ and α also represent the probability of eliminating uncertainty under each choice, the condition $\gamma < \alpha$ means that the package is less informative than seed only. For a farmer to sequentially adopt seed first and then the seed-fertilizer package, the adoption of seed only must be more informative about the validity of the agent's report than the adoption of the package. Analogous results hold for adoption of fertilizer only.

The model reveals some interesting insights into the adoption patterns described in empirical work. A δ^1 sufficiently close to one, which denotes high confidence in the success of the package, ensures that sequential adoption will not occur. If the extension agent is right, and when farmers have other sources of information such as neighboring farmers, the model suggests that early adopters may adopt parts of the package sequentially, while later adopters, whose δ^1 's have been raised by the positive experience of neighbors, adopt the whole package.

The model also demonstrates why farmers in one region tend to adopt a part of the package first, while farmers in another region tend to adopt

another. In circumstances where $E_S^1 > E_B^1$ and $E_F^1 > E_B^1$, the farmer will adopt seed first if $E_S^1 - E_F^1 > 0$ and fertilizer first if $E_S^1 - E_F^1 < 0$. The order of adoption is determined by the sign of

$$E_S^1 - E_F^1 = [\psi_S - \psi_F] + (1 - \delta^1)\mu_B(\beta - \alpha),$$

and will vary between two regions if the corresponding ψ_S , ψ_F , μ_B , α , and β differ. Differences in the general pattern of adoption are explained by differences in the economic or agroclimatic environment that affect the profit distribution associated with each choice of technique.

The order of adoption, or the sign of $E_S^1 - E_F^1$, is also affected by δ^1 , the farmer's perceived probability that the extension report is accurate. If $\psi_S > \psi_F$ and $\beta > \alpha$, seed alone generates higher expected returns in the first period, but fertilizer alone provides more information. In this case, a farmer with a low δ^1 may choose fertilizer in the first period, while another farmer, identical to the first except for δ^1 , chooses seed. Farmers with similar characteristics but differing prior judgments about the reliability of the extension report may choose to adopt different components. Thus, the model can explain why farmers facing the same economic and ergonomic conditions choose different adoption sequences.

Finally, the model indicates that farmers may choose to adopt a particular technique because they are willing to pay for information to avoid making a mistake in subsequent periods. For example, when ψ_B is negative, the farmer's judgment is that expected profits in a period will be maximized by using traditional production techniques. The farmer may nevertheless adopt a part or all of the package in the first period if the expectation, E^1 , is positive for that choice. The farmer is willing to pay for information in the first period to avoid making a mistake in the second period.

The analytical results of the model are not grounded in assumptions about the degree of input complementarity, and even when inputs demonstrate profit-rate complementarity, all of the cases described can be realized. As formulated, the results do not depend on capital or credit constraints that curtail input purchases or on risk-averse behavior.

Concluding Comments

Sequential or stepwise adoption of parts of a technological package has been observed in a

variety of settings, but the reasons behind it are only partially understood. The model presented in this paper is consistent with the behavior described by informed observers; it presents a plausible explanation for sequential adoption even under the assumptions of risk neutrality and unconstrained expenditures. According to this explanation, a farmer is uncertain about whether the new production techniques will be successful on his/her farm, and experimentation with techniques will not always resolve this uncertainty. Under some circumstances, the farmer may learn more about the innovation as a whole by adopting only a part of the recommended package. The model can explain why patterns of sequential adoption differ among agroecological regions, as well as among neighboring farmers operating under similar conditions. Unlike the credit constraint explanation described earlier, the Bayesian approach explains sequential adoption even when the profit rate from adopting the package is greater than with any component.

The model supports the perspective that sequential adoption may be a rational choice for imperfectly informed farmers and need not be viewed as evidence of institutional shortcomings or farmer irrationality. If sequential adoption is a response to uncertainty on the part of farmers, the appropriate policy question is whether sequential adoption is the least-cost way of providing information to farmers.

On Testing the Structure of Risk Preferences in Agricultural Supply Analysis

Rulon D. Pope and Richard E. Just

Risk preferences broadly affect many economic decisions when markets are incomplete. Common representations of risk preferences are constant absolute, relative, and partial relative risk aversion. Each of these preference classes has distinct impacts on choice. An econometric test for distinguishing the class of preferences is proposed and implemented for potato supply response in Idaho. The data reject constant absolute and partial relative risk aversion and are congruent with constant relative risk aversion.

Key words: risk, risk preferences, supply response.

The model of the price-uncertain, competitive, single-product firm has received much attention in a wide variety of theoretical analyses (e.g., Sandmo, Katz, Briys and Eeckhoudt, Ishii, Hey, Chavas and Pope). A rather complete set of theoretical restrictions has emerged which depends crucially on risk preferences. Three classes emerge as important benchmarks: constant absolute risk aversion (CARA), constant relative risk aversion (CRRA), and constant partial relative risk aversion (CPRRA). These three classes are important not only for null hypotheses from which to accept (or reject) rising or falling risk aversion but are important in their own right. For example, these three classes imply, respectively, (a) changes in the location of initial wealth do not alter decisions, (b) changes in the scale of wealth do not affect decisions, and (c) changes in profit or the scale of the bet do not alter decisions. Each of these implications has important ramifications. For example, CARA is crucial to exact welfare analysis (Pope, Chavas, and Just), while CRRA implies that a proportional wealth tax or wealth sharing does not alter decisions. For CPRRA, the scale of, or the existence of, profit sharing or tax would not affect decisions (Pope).

In addition to this conceptual work, a growing body of empirical work has found evidence of risk aversion and risk response. This includes both firm-level and aggregate analysis (compare

Binswanger, Just, Holland). In both approaches, important information is obtained. Firm-level analysis suffers from less aggregation bias and filters and controls extraneous factors more directly. However, aggregate analysis generally gives the kinds of measures that are needed for policy analysis. The econometric evidence in Hansen and Singleton, Friend and Blume, Siegel and Hoban, Wolf and Pohlman, and Szpiro finds support for risk-averse behavior; but whether risk aversion is constant, decreasing, or increasing remains ambiguous. Decreasing absolute risk aversion has emerged as a "stylized" fact or belief, but the nature of relative and partial relative risk aversion is in dispute.

This paper focuses on the econometric approach to risk response behavior for both the individual and aggregate levels and both the single and multiproduct cases. Simple statistical tests for CARA, CRRA, and CPRRA are discussed and applied. These tests use only reduced-form econometric models of the type commonly employed in agricultural economics research. They are implemented only within a single equation.¹ These tests are applied to a potato acreage response model for the state of Idaho. Strong evidence is found against the hypotheses of risk neutrality, CARA, and CPRRA. The data lends credence to the hypothesis of CRRA.

Rulon D. Pope is a professor of economics, Brigham Young University; Richard E. Just is a professor of agricultural and resource economics, University of Maryland.

¹ This is important because integrability of decision functions (rationalizing expected utility from multiple choices) in a production system is only attained in very specific risk models (e.g., Just and Pope, Antle).

The Firm's Decisions

The model used here is the netput model of the competitive firm (McFadden). Profit, π , is $p'X$, where p is a vector of random prices and X_i is a supply ($X_i > 0$) or derived-demand level ($X_i < 0$), $i = 1, \dots, N$. Initial wealth is assumed nonrandom and is denoted by W_0 . Hence, final wealth, W , is $W = W_0 + \pi$. Decisions are made *ex ante* by maximizing expected utility of wealth, $E[U(W)]$, subject to the feasibility condition (production possibility set and/or capital constraint) $T(X) = 0$, where U is utility; $E[U(W)]$ and T are assumed smooth in X and relevant moments of the random price vector, p .

Given these assumptions, the optimal choices are characterized by

$$(1) \quad \begin{aligned} E[U_w(W)p] + \lambda T_X(X) &= 0, \\ T(X) &= 0, \end{aligned}$$

where subscripts denote derivatives and λ is a Lagrangian multiplier. Solution of (1) yields optimal decisions X^* .

In empirical work, the distribution of p is assumed to be summarized parametrically by $\{M_1, \dots, M_s\}$, where each M_s is a vector representing all moments of order s .² In this case, direct expected utility can be expressed as $E[U(W)] = V(X, W_0, M_1, \dots, M_s)$ with optimal decisions.

$$(2) \quad X^*(W_0, M_1, \dots, M_s).$$

The essential nature of the problem here is that W is linear in p (but not X). Thus, the basic capital budgeting or portfolio problem is a special case.³

The three risk aversion measures explored here are

$$\frac{-U''(w)}{U'(w)} \quad \text{absolute risk aversion}$$

$$\frac{-U''(w)w}{U'(w)} \quad \text{relative risk aversion}$$

$$\frac{-U''(w)\pi}{U'(w)} \quad \text{partial relative risk aversion}$$

The first two measures are found in Arrow and Pratt, and the latter is from Menezes and Hansen.

A number of authors have applied expected utility models of the firm to profit instead of wealth (e.g., Sandmo, Binswanger, Antle). In such cases relative and partial risk aversion are identical. Katz has argued that any measure using only profit as the argument of utility (such as partial relative risk aversion) is inappropriate since profit can be negative. Hey refutes Katz but shows that the possibility of negative profit merely imposes restrictions on U . For example, constant absolute risk aversion yields risk-prefering behavior in the region of negative profit (Hey).

Testing for Specific Forms of Risk Aversion

As Pratt, Sandmo, and others have observed, changes in W_0 leave X^* unchanged under CARA. This provides a straightforward test for CARA. Turning to CRRA, a simple test can be developed by examination of (1). From Pratt (p. 134), if wealth is scaled by γ , $U(\gamma W)$ and $U(W)$ represent the same ordering under CRRA. This leads to the class of Cobb-Douglas utility functions in wealth. Therefore, if wealth is scaled by γ , the first-order conditions in (1) are effectively unaltered as is X^* . A similar argument can be made for CPRRA (Menezes and Hansen). If π is scaled by γ under CPRRA, X^* is unaltered. This leads to the class of Cobb-Douglas utility functions in profit.

These results hold regardless of the form of W . However, writing W as $W_0 + p'X$ allows simple and specific behavioral propositions which can be implemented easily. Scaling terminal wealth by γ is equivalent to scaling both initial wealth, W_0 , and prices, p , by γ . Furthermore, scaling p by γ is equivalent to scaling all moments M_s by γ^s .⁴

These results imply

² The moments are assumed to exist. Most empirical work includes only M_1 and M_2 , for example, where the class of stochastic distributions is restricted to normality (see the empirical references cited above). The methodology here is more generally restricted to a class of stochastic distributions that are completely characterized by a finite set of moments.

³ For example, in one special case the individual or firm solves $\max E[U(W)]$ subject to $\sum_{i=1}^N X_i \leq W_0$, where p_i is interpreted as the return on one invested dollar in activity i . In a common agricultural case, the farmer solves $\max E[U(W)]$ subject to $\sum_{i=1}^N X_i \leq \bar{A}$, where \bar{A} is available acreage, X_i is the acreage allocated to crop i , and p_i is the net returns per acre from farming crop i .

⁴ Where an element of M_s is given by

$$\begin{aligned} M_s^k(p) &= E(p_1 - E(p_1))^{\alpha_1} (p_2 - E(p_2))^{\alpha_2} \dots (p_N - E(p_N))^{\alpha_N}, \\ \sum_{i=1}^N \alpha_i &= s, \text{ scaling } p = (p_1, \dots, p_N)' \text{ by } \gamma \text{ obtains } M_s^k(\gamma p) \\ &= \gamma^s M_s^k(p). \end{aligned}$$

$$(3) \quad X^*(\gamma W_0, \gamma M_1, \gamma^2 M_2, \dots, \gamma^s M_s) \\ = X^*(W_0, M_1, M_2, \dots, M_s).$$

That is, under CRRA decisions in (2) are almost homogenous of degree one in initial wealth and the means of p , of degree two in the second moment of p , and degree s in the s th moment of p .⁵ As in common tests for homogeneity, a Euler equation corresponding to (3) is useful for testing CRRA.

PROPOSITION 1. *Under CRRA, decisions in (2) follow the vector equation:*

$$(4) \quad \left(\frac{\partial X^*}{\partial W_0} \right) W_0 + \sum_{s=1}^s \left(\frac{\partial X^*}{\partial M_s} \right) M_s = 0, \text{ or} \\ \left(\frac{\partial \ln X^*}{\partial \ln W_0} \right) + \sum_{s=1}^s \left(\frac{\partial \ln X^*}{\partial \ln M_s} \right) s = 0,$$

where appropriate.

Proof: Differentiate (3) with respect to γ and evaluate at $\gamma = 1$ (Pope).

Thus, for example, if one estimates (2) in linear logarithmic form, the weighted sum of the elasticities in (4) must equal zero. The weights are the order of the moments. Equation (4) can be imposed locally by imposing (4) at a point $(\bar{W}_0, \bar{M}_1, \dots, \bar{M}_s)$.

The analysis for CPRRA is similar. Scaling π by γ is equivalent to scaling all moments M_s by γ^s , which implies

$$(5) \quad X^*(W_0, \gamma M_1, \dots, \gamma^s M_s) \\ = X^*(W_0, M_1, \dots, M_s).$$

Thus, under CPRRA, decisions in (2) are almost homogenous of degree one in the means of p , of degree two in the second moment of p , and degree s in the s th moment of p .

PROPOSITION 2. *Under CPRRA, decisions in (2) follow the vector Euler equation*

$$(6) \quad \sum_{s=1}^s \left(\frac{\partial X^*}{\partial M_s} \right) M_s = 0.$$

Proof: Similar to proposition 1.

Again (6) can be imposed locally for local tests of CPRRA. Finally, a well-known result is stated.

PROPOSITION 3. *Under CARA, initial wealth does not alter decisions, or*

$$(7) \quad \frac{\partial X^*}{\partial W_0} = 0.$$

A simple example will illustrate how propositions 1, 2, and 3 can be applied in testing for CARA, CRRA, and CPRRA. Suppose that p_1 is random and $X_1^* > 0$ with p_2, \dots, p_N nonrandom and $X_2^*, \dots, X_N^* < 0$. This is the Sandmo model. Assuming p_1 is normally distributed, decisions are completely characterized by the mean of p_1 , $E(p_1) = \mu$; σ^2 , the variance of p_1 ; p_2, \dots, p_N ; and W_0 . Under CARA, expected utility is maximized by equivalently maximizing $\mu X_1 + \sum p_j X_j - (r/2) X_1^2 \sigma^2$ subject to $T(X) = 0$ (Freund). Thus, $\partial X^* / \partial W_0 = 0$ since initial wealth does not enter the decision. Further, because the objective function in this particular case is linearly homogenous in μ , p_2, \dots, p_N and σ^2 , the following three tests under normality are appropriate:

$$(8) \quad \frac{\partial W^*}{\partial W_0} = 0, \frac{\partial X^*}{\partial \mu} \mu + \sum_{j=2}^N \left(\frac{\partial X^*}{\partial p_j} \right) p_j \\ + \left(\frac{\partial X^*}{\partial \sigma^2} \right) \sigma^2 = 0 \text{ for CRRA}$$

$$(9) \quad \frac{\partial W^*}{\partial W_0} W_0 + \left(\frac{\partial X^*}{\partial \mu} \right) \mu + \sum_{j=2}^N \left(\frac{\partial X^*}{\partial p_j} \right) p_j \\ + 2 \left(\frac{\partial X^*}{\partial \sigma^2} \right) \sigma^2 = 0 \text{ for CARA}$$

$$(10) \quad \left(\frac{\partial X^*}{\partial \mu} \right) \mu + \sum_{j=2}^N \left(\frac{\partial X^*}{\partial p_j} \right) p_j \\ + 2 \left(\frac{\partial X^*}{\partial \sigma^2} \right) \sigma^2 = 0 \text{ for CPRRA.}$$

The first restriction in (8) always occurs under CARA, whereas the second restriction is specific to CARA under normality. It is interesting to contrast the Euler equations in (8)–(10) with those occurring under certainty or risk neutrality. Under certainty or risk neutrality, all wealth and variance effects are omitted. Thus, both certainty and risk neutrality are special cases of all three conditions. Finally, note that the variance term has weight one under CARA and two under CRRA and CPRRA.

An Application

The risk response models developed by Just and others are applied here to potato production in

⁵ Here we use the concept of almost homogeneity used, for example, by Lau (p. 173): A function $h(z_1, \dots, z_N)$ is said to be almost homogenous of degree c_1, \dots, c_N , and zero if $h(\gamma^{c_1} z_1, \dots, \gamma^{c_N} z_N) = \gamma h(z_1, \dots, z_N)$ where $\gamma \in R$. Here we consider γ to be positive and is thus positively almost homogenous.

Idaho to test for the structure of risk preferences in parsimonious reduced-form models such as (8)–(10). Potatoes have been of longstanding interest to economists; their highly erratic prices have made potatoes a prime candidate for the analysis of perverse demand behavior (Dwyer and Lindsay), dynamic supply analysis (Zusman), and risk response (Estes, Blakeslee, and Mittelhammer).

The model specification is

$$(11) \quad A_p = B_0 + B_1 W_0 + B_2 P_p^e + B_3 P_s^e + B_4 V_p^e + B_5 V_s^e + B_6 C^e + \epsilon,$$

where all variables are T vectors with $\epsilon \sim N(0, \sigma^2 I_T)$, i.e., ϵ_t is identically and independently distributed, A_p is potato acreage, the B 's are parameters to estimate; the subscripts p and s represent potatoes and sugar beets, respectively; and superscript e represents the subjectively formed moments of output prices, where P^e is mean price, V^e is variance of price, and C^e is covariance of prices.⁶ Letting t denote time, the first two moments are defined as in Just:⁷

$$(12) \quad P_{jt}^e = \theta \sum_{k=0}^K (1 - \theta)^k P_{j,t-k-1}; j = s, p,$$

$$(13) \quad V_{jt}^e = \theta \sum_{k=0}^k (1 - \theta)^k (P_{j,t-k-1} - P_{j,t-k-1}^e)^2;$$

$$j = s, p,$$

$$(14) \quad C_t^e = \theta \sum_{k=0}^k (1 - \theta)^k \{ [P_{j,t-k-1} - P_{j,t-k-1}^e] [P_{j',t-k-1} - P_{j',t-k-1}^e] \} j \neq j', j = s, p$$

and can be rationalized as a Bayesian learning process where θ is a parameter. Though the debate over rational versus adaptive expectations leads to important criticisms of the adaptive model, the choice of adaptive expectations is necessitated by the fact that market-level data are not analyzed. Further, there is no futures market for potatoes, and thus using spot prices to form expectations for the price of potatoes is reasonable.

The time-series data are Idaho state-level data extending from 1950 through 1987.⁸ The first

six observations are used as a history for the adaptive expectations framework. Thus, the model is estimated with thirty-two observations. The measure of wealth is the value of land and buildings minus associated debts. Total state potato acreage is the dependent variable, and all the independent variables in (11) are normalized by prices paid for agricultural inputs in production. All variables are then normalized by their respective means. This implies that parameter estimates in a linear regression are elasticities at the average level of the variables.

The results from nonlinear regression are presented in table 1. The adaptive parameter θ is estimated in the unit interval with a fairly high level of memory indicated in the expectation scheme. The coefficients, $B_0 - B_4$ and θ have the expected signs. The sign of B_5 is counterintuitive when the covariance term is included but is insignificant. It changes to a plausible sign when the covariance term is excluded. In general, based upon the signs and precisions of coefficient estimates, the model with covariance excluded seems better specified.

The sign of B_6 in the first column is indeterminate so a positive value or zero is not implausible. That is, an increase in covariance tends to reduce diversification and leads to more specialization in the crop with higher expected returns. Potatoes are apparently that crop. Generally t -ratios are large, lending strong evidence (99% confidence) that wealth and own expectations and variance are significant explanatory variables. The evidence is less strong for inclusion of cross-price effects.

Based upon the individual t -tests for $H_0: B_4, B_5, B_6 = 0$, it appears that the hypothesis of risk neutrality ($B_4 = B_5 = B_6 = 0$) is soundly rejected. Indeed, a likelihood ratio test of the joint hypothesis yields a statistic of 9.6. This exceeds the chi-square tabled value of one degree of freedom at the .01 significance level. Wealth is positively related to potato acreage ($B_1 > 0$) and is highly significant, *ceteris paribus*. Thus, CARA is rejected in favor of nonconstant absolute risk aversion. The results also suggest rejection of CPRRA. Thus, omission of wealth effects in empirical research may bias estimates of responses including risk effects. Because such wealth effects are routinely omitted in agricultural research, opportunities for exploring risk preferences and measuring properly risk response properly are lost.

Table 2 contains the test results of the three hypotheses similar to (8)–(10). As noted earlier, these results soundly reject the hypothesis of

⁶ Antle (1987) has stressed that inclusion of higher moments should be investigated. However, convergence with even two moments is difficult.

⁷ All estimations assumed a single θ parameter in (12)–(14). The use of a single θ parameter is supported by the work of Just.

Table 1. Potato Supply Response—Idaho

	Coefficient	With Covariance	Without Covariance
Intercept	B_0	-.2350 (.4559)	.0192 (.2452)
Wealth	B_1	.6831 (.0774)	.6651 (.0802)
Price expectation—potatoes	B_2	2.6548 (.7327)	2.9378 (.6537)
Price expectation—sugar beets	B_3	-1.2209 (1.7610)	-2.0751 (.2314)
Variance—potatoes	B_4	-1.6801 (.61433)	-1.1971 (.330)
Variance—sugar beets	B_5	-.7385 (1.8857)	1.0103 (.2205)
Covariance	B_6	2.2339 (2.0709)	
Adaptive parameter	θ	.3258 (.1540)	.4205 (.2169)
SSR		.2310	.2438
R^2		.77	.77

Notes: Standard errors in parentheses are computed using the information matrix. The Hessian of the sum of squares is divided by $2\hat{\sigma}^2$. The negative of the inverse of the resulting matrix is the information matrix derived from the log likelihood function. Coefficient estimates are elasticities at sample means.

CARA at the 1% level. They also reject the hypothesis of CPRRA at the 1% level. Not only does wealth enter utility, but the Euler equation in (6) significantly raises the likelihood function. The hypothesis of CRRA cannot be rejected at this level. In the model with covariance deleted, which seems to be well specified empirically, the evidence against the CRRA hypothesis is very weak. Thus, the intuitive arguments of Arrow favoring CRRA may be useful.

Concluding Comments

Although much has been said about the impact of the structure of risk preferences on behavior,

virtually no empirical work examines risk structure in reduced-form demands or supplies except to test for the mere existence of risk aversion. As shown here, much more can be obtained from empirical models of risk response. Simple Euler equations that generalize the case of homogeneity can be used to refute constant relative, partial relative, or absolute risk aversion using only reduced-form equations that can be estimated econometrically using supply and demand data.

These data reject the common practice of omitting wealth data in models of producer response and are consistent with similar findings of Chavas and Holt. Policies which affect initial wealth, such as tax policies or sugar policy, will

Table 2. Test Results for CARA, CRRA, and CPRRA

Test	t and F Statistics ^a	Significance Level ^b
Model 1—with covariance term		
CARA	10.1870	<.0001
CRRA	2.1636	.0203
CPRRA	18.7675	<.0001
Model 2—without covariance term		
CARA	9.8257	<.0001
CRRA	1.2648	.1088
CPRRA	22.0638	<.0001

^a These tests are conducted at the sample means of initial wealth, price expectations, variances and covariances. Because testing for CARA is obtained by inspection of table 1, simple t -tests are used. This is asymptotically equivalent to the likelihood ratio test under our assumptions. For CRRA and CPRRA, asymptotic t and F tests, respectively, are used which are equivalent to likelihood ratio tests in large samples.

^b Significances are calculated with 24 degrees of freedom for model 1 and 25 degrees of freedom for model 2. Thus, the asymptotic tests are applied conservatively.

impact profit both directly and indirectly through initial wealth. Constant relative risk aversion has a number of modeling implications. These preferences and the log normality of wealth yields a very tractable model of choice (Hansen and Singleton). Second, risk sharing which scales wealth will have no effect on choice. Thus, denominating wealth in real or nominal terms leads to identical models of choice. Any policy change that proportionally alters final wealth similarly leaves decisions unchanged.

Factor Price Stabilization and the Competitive Firm

S. Devadoss and E. Kwan Choi

This paper investigates the effects of factor price stabilization on production decisions of the competitive firm with *ex post* production flexibility. Factor price stabilization is achieved through changes in the guaranteed minimum price and the imposed maximum price. For the risk-averse firm, the effect of factor price stabilization, through a mean-preserving contraction, on capital crucially depends on whether capital and the variable input are substitutes or complements as well as the observable characteristics of the variable input demand curve.

Key words: factor price stabilization, risk aversion.

It is well known that price uncertainty has an adverse impact on the supply of a risk-averse competitive firm which makes output decisions before observing the market price (Baron and Sandmo). Many agricultural price stabilization programs are designed to reduce price uncertainty. In the United States, the nonrecourse loan program provides downside price protection to grain producers, whereas the Farmer-Owned Reserve (FOR) program limits the upward movements of prices (Wright 1985). Similarly, the European Community price support mechanism stabilizes the grain prices between intervention and target prices (Eeckhoudt and Hansen).

The literature which studies the impacts of price uncertainty on the supply side is abundant. For example, Turnovsky showed that price uncertainty may not have a negative impact on the planned output of a risk-averse firm with *ex post* production flexibility. In the same spirit, Hartman (1976) introduced a two-factor model in which capital is a quasi-fixed input and determined *ex ante*, but the variable input is chosen after the uncertainty is resolved.

In a market equilibrium framework, price uncertainty of a primary commodity not only affects the supply side, as investigated by Baron and Sandmo, but also affects the demand side

because primary commodities are used as inputs in other industries. Subsequent literature in this area, as summarized by Robison and Barry, has examined the effects of input price uncertainty on production decisions of the competitive firm. Stewart employed a two-factor model to show that if both factors are determined *ex ante* under input price uncertainty, a risk-averse firm uses less of the risky input and more of the riskless input than a risk-neutral firm. Perrakis has shown that with *ex post* input flexibility input price uncertainty introduces a definite bias on factor demands even for risk-neutral firms.

In a recent study Wright (1984) considered a competitive firm with flexibility in both the variable input and output, and analyzed the effects of input price uncertainty on factor demands of a risk-neutral firm.¹ He showed that "the response of the quasi-fixed factor, and the expected short-run response of the variable factor, are directly related to observable characteristics of the input demand and output supply functions" (p. 443). Specifically, he showed that input price uncertainty increases (decreases) the optimal level of the quasi-fixed input of a risk-neutral firm if the slope of the variable input demand curve becomes flatter (steeper) as the quasi-fixed input increases. Wright's analysis represents an important contribution to the theory of the competitive firm with *ex post* production flexibility.

The purpose of this paper is to investigate the effects of factor price stabilization policies on

S. Devadoss and E. Kwan Choi are, respectively, an adjunct assistant professor and an associate professor, Department of Economics, Iowa State University.

Journal Paper No. J-14256 of the Iowa Agriculture and Home Economics Experiment Station Project No. 2681.

The authors are indebted to two anonymous referees for their insightful comments. The usual caveats apply.

¹ Wright also considered output price uncertainty.

input demands and output supply of the competitive firm with *ex post* production flexibility. The firm is assumed to use primary commodities (e.g., corn and wheat) as inputs. The distinguishing feature of this study is that the random input price is bounded by guaranteed minimum (floor) and imposed maximum (ceiling) prices. Factor price stabilization is implemented by a mean-preserving contraction (MPC) in the input price by changing the price floor and ceiling simultaneously. This type of MPC was first proposed by Eeckhoudt and Hansen to analyze the effect of a marginal change in output price uncertainty on supply. This approach captures the essence of stylized price stabilization policies widely adopted in the United States and the European Economic Community (EEC). For example, U.S. price support programs generally limit the movements of corn and wheat prices between the price floor (loan rate) and price ceiling (release price). Similarly, the EEC generally stabilizes domestic prices between intervention and target prices.

The paper is organized as follows. The second section presents the properties of the variable input demand and the short-run supply functions. The third section considers a risk-averse firm and examines the effects of changes in maximum and minimum prices on the optimal level of capital. The effects of an MPC on capital, expected variable input, and expected output supply are also included. The paper ends with a summary and concluding remarks.

Short-Run Behavior of the Competitive Firm

To lay the basis for analyzing the effects of input price uncertainty on factor demands, in this section we examine the short-run production decisions of the competitive firm with *ex post* input and output flexibility. The competitive firm produces a homogenous product Q , using capital input K and a variable input X . The production function $Q = F(K, X)$ is assumed monotone increasing and strictly concave in inputs in the relevant range.

Assume that capital input price, c , is known, but the price of the variable input price, r , is random with density function $g(r)$ and cumulative distribution function $G(r)$. The inputs are supplied in the domestic market. Output Q may be sold in the domestic or foreign market at the world price p . While the random input price r induces a fluctuation in the aggregate domestic

supply of Q , the domestic market is assumed to be small and the world price p is fixed and independent of the random domestic factor price r .²

The capital input is a quasi-fixed factor, i.e., K must be chosen *ex ante* before the input price r is known. In contrast, the variable input X is purchased *ex post*, i.e., after the random input price is observed. The risky input X represents a domestic factor such as corn or wheat, whose price is stabilized by commodity programs. Corn and wheat are used as inputs in the food-processing industry and also in the livestock sector. The capital input K can be viewed as plant size or number of animals placed on feed.³

The firm may engage in forward contracting, which is important in the food processing and livestock sectors. Entering the forward market does not preclude the firm from buying or selling the input in the spot market. It is well known that the separation result holds for the supplier, i.e., the output decision of the producer of X is not affected by the distribution of r or risk attitude (Danthine). However, it can be shown that the separation result will not hold for a producer who demands X as an input, because the firm has *ex post* production flexibility. Incorporating the futures contracts considerably complicates the analysis without yielding additional insights. Thus, we focus on the effects of factor price stabilization on optimal production decisions.

After the risky input price r is observed, the firm's problem *ex post* is to choose X to maximize the short-run surplus,

$$(1) \quad \pi = pF(K, X) - rX.$$

The first-order condition is $pF_X(K, X) - r = 0$. The short-run variable input demand function can be written $X = X(K, p, r)$.

We examine how the variable input demand is affected by changes in r and K . The following properties of the variable input demand function are obtained from the first-order condition:

$$(2a) \quad \partial X / \partial r = 1 / pF_{XX} < 0,$$

$$(2b) \quad \partial X / \partial K = -F_{KX} / F_{XX}.$$

Because the production function is concave in X , F_{XX} is negative and hence $\partial X / \partial r < 0$ in (2a).

² For a large economy, the world price should fluctuate with the domestic random input price. However, as Wright (p. 443) noted, the analysis of input price instability along with induced random output price considerably complicates the analysis because of the short-run production flexibility.

³ See Jarvis, and Chavas and Klemme for considering livestock animals as capital input.

K and X are complements (substitutes) if F_{KX} is positive (negative). Equation (2b) indicates that an increase in capital will shift the variable input demand curve to the right (left) if the two inputs are complements (substitutes).

Next, consider how the short-run output supply responds to changes in r and K . Substituting $X(K, p, r)$ into the production function yields the short-run supply function, $Q(K, p, r) = F[K, X(K, p, r)]$. Differentiating Q with respect to r and K gives

$$(3a) \quad \partial Q / \partial r = r / p^2 F_{XX} < 0,$$

$$(3b) \quad \partial Q(K, p, r) / \partial K = F_K - F_X(F_{KX} / F_{XX}).$$

If the two factors are complements, then $\partial Q / \partial K$ is positive. However, if the two factors are substitutes, then $\partial Q / \partial K$ can be negative. Using a cost minimization problem for a given output, Hartman (1975, p. 1290) notes that $F_K - F_X(F_{KX} / F_{XX})$ is positive (negative) if K is a normal (an inferior) factor. Henceforth, K is assumed to be a normal input.⁴

Substituting $X(K, p, r)$ into (1) gives $\pi(K, p, r) = pF(K, X(K, p, r)) - rX(K, p, r)$. This surplus function is nondecreasing in p and nonincreasing in r , convex in (p, r) and for given K it is linearly homogenous in (p, r) . The following properties of the surplus function are obtained using the envelope theorem:

$$(4a) \quad \partial \pi / \partial K = pF_K(K, X(K, p, r)),$$

$$(4b) \quad \partial \pi / \partial p = Q(K, X(K, p, r)),$$

$$(4c) \quad \partial \pi / \partial r = -X(K, p, r),$$

where $pF_K(K, X(K, p, r))$, $Q(K, X(K, p, r))$, and $X(K, p, r)$ are the value of marginal product of capital, the short-run supply, and the short-run variable input demand, respectively.

If the competitive firm employs its variable input optimally *ex post*, then the profit function is given by

$$(5) \quad \Pi(K, p, r, c) = pF(K, X(K, p, r)) - rX(K, p, r) - cK = \pi(K, p, r) - cK.$$

The results in this section will be used to analyze the impact of a marginal change in the input price uncertainty on production decisions of a risk-averse competitive firm.

Factor Price Stabilization and Risk Aversion

In this section we consider production decisions of a risk-averse competitive firm which faces the random input price r . To facilitate the exposition, we first investigate the effects of small changes in maximum and minimum prices of the variable input X on the optimal level of capital. The effects of an MPC through maximum and minimum prices on the optimal level of capital, the expected responses of the variable factor, and output supply are then examined. The results show that substitutability and complementarity between capital and the variable input play a key role in determining the effects of factor price stabilization through an MPC on the optimal level of capital of a risk-averse firm.

If there are no maximum and minimum price bounds on the random input price r , then a risk-averse competitive firm's problem is to choose K to maximize the expected utility,

$$(6) \quad \begin{aligned} \text{Max}_K \quad & EU[\Pi(K, p, r, c)] \\ &= \int_0^\infty U[\pi(K, p, r) - cK] dG(r), \end{aligned}$$

where $U(\cdot)$ is a monotone-increasing and strictly concave von Neumann-Morgenstern utility function, i.e., $U'(\Pi) > 0$, $U''(\Pi) < 0$. The first-order condition is

$$E[U' \Pi_K] = \int_0^\infty [U'(\pi_K - c)] dG(r) = 0.$$

The second-order condition requires that $EU_{KK} = E[U''(\Pi_K)^2 + U' \Pi_{KK}] < 0$.

Consider a commodity program which stabilizes the input price r . Specifically, the government intervenes in the market for X through buffer stocks so that the random input price r does not fall below a guaranteed minimum price, r_m , or rise above an imposed maximum price, r_M . This implies that r is allowed to fluctuate only between the r_m and r_M , and hence the density function $g(r)$ is truncated at r_m and r_M . In general the distribution $G(r)$ is contingent upon the aggregate supply of X . If a change in the minimum or maximum price affects the industry supply of X , it will also affect the distribution $G(r)$ (Wright and Williams). However, to focus on the firm-level analysis, we adopt the convention, as in Eeckhoudt and Hansen, that the distribution $G(r)$ is unaffected by changes in r_m or r_M .

⁴ If K represents the "size" of the firm (or number of animals), it is unlikely for a small firm to produce more output than a larger firm. We have yet to find an anomalous quasi-fixed input that is inversely related to total output.

Maximum Price

The analysis begins by considering the optimal choice of capital for a risk-averse firm when a ceiling price r_M is imposed on the random input price r . The risk-averse competitive firm's problem is to choose K to maximize the expected utility,

$$(7) \quad A^M = \int_0^{r_M} U[\pi(K, p, r) - cK]dG(r) + U[\pi(K, p, r_M) - cK](1 - G(r_M)),$$

where $(1 - G(r_M))$ is the cumulative probability that the random price r is greater than the maximum price, r_M . Using (4a), the first-order condition is

$$(8) \quad dA^M/dK = B^M(K, p, c, r_M) = \int_0^{r_M} U'[pF_K(K, X(K, p, r)) - c]dG(r) + U'_{r_M}[pF_K(K, X(K, p, r_M)) - c](1 - G(r_M)) = 0,$$

where U'_{r_M} indicates that U' is evaluated at the profit level for the sure price r_M . The function B^M indicates that dA^M/dK depends on K , p , c and r_M .

Let K^a denote the optimal level of capital of the risk-averse firm. Observe that for the first-order condition to hold, the optimum level of capital K^a satisfies the inequality,

$$(9a) \quad pF_K(K, X(K, p, r_M)) > c$$

if K and X are substitutes ($F_{KX} < 0$). Note that $F_{EX} < 0$ implies that $pF_K(K, X(K, p, r)) < pF_K(K, X(K, p, r_M))$ for $r < r_M$. The inequality in (9a) is proved by contradiction: If $pF_K(K, X(K, p, r_M)) \leq c$, then $pF_K(K, X(K, p, r)) < c$. If this were the case, (dA^M/dK) would be negative and the first-order condition (8) would not be satisfied. Thus, the inequality (9a) holds. By similar reasoning, one can verify that for the first-order condition to hold,

$$(9b) \quad pF_K(K, X(K, p, r_M)) < c$$

if K and X are complements ($F_{KX} > 0$).

Totally differentiating the function $B^M(K, p, c, r_M)$, we note that at the optimum $(\partial B^M/\partial K)dK + (\partial B^M/\partial r_M)dr_M = 0$. Solving for dK/dr_M and observing that $\partial B^M/\partial K$ is negative by the second-order condition, we get

$$\text{sign}(dK/dr_M) = \text{sign}(\partial B^M/\partial r_M).$$

To determine the sign of $(\partial B^M/\partial r_M)$, we differentiate the first-order condition (8) with respect to r_M and obtain, after rearranging terms,

$$(10) \quad (\partial B^M/\partial r_M)(1/(1 - G(r_M))) = U'_{r_M}(-X) \cdot [pF_K(K, X(K, p, r_M)) - c] + U'_{r_M} \cdot pF_{KX}(K, X(K, p, r_M))(\partial X/\partial r_M).$$

Using the results in (9a) and (9b), we see that $\partial B^M/\partial r_M$ is positive (negative) if K and X are substitutes (complements). Therefore, an increase in the maximum price r_M increases (decreases) the optimal level of capital if the two inputs are substitutes (complements).

Minimum Price

We now consider the optimal choice of capital for a risk-averse firm when a guaranteed minimum price r_m is imposed on the random input price r . The firm's problem is to choose K to maximize the expected utility

$$(11) \quad A^n = U[\pi(K, p, r_m) - cK]G(r_m) + \int_{r_m}^{\infty} U[\pi(K, p, r) - cK]dG(r).$$

The first-order condition is

$$(12) \quad dA^n/dK = B^n(K, p, c, r_m) = U'_{r_m} \cdot [pF_K(K, X(K, p, r_m)) - c]G(r_m) + \int_{r_m}^{\infty} U' \cdot [pF_K(K, X(K, p, r)) - c]dG(r) = 0,$$

where U'_{r_m} indicates that U' is evaluated at the profit level for the sure price r_m . As for the maximum price, it should be noted that for the first-order condition (12) to hold, the optimum level of capital K^a must satisfy the inequality,

$$(13) \quad pF_K(K, X(K, p, r_m)) < (>) c$$

if K and X are substitutes (complements).

To determine the effect of a change in the minimum price r_m on the optimal level of capital, we totally differentiate the function $B^n(K, p, c, r_m)$ and note that at the optimum $(\partial B^n/\partial K)dK + (\partial B^n/\partial r_m)dr_m = 0$. Because $(\partial B^n/\partial K)$ is negative, we observe that

$$\text{sign}(dK/dr_m) = \text{sign}(\partial B^n/\partial r_m).$$

To evaluate the sign of $(\partial B^n/\partial r_m)$, we differentiate the first-order condition (12) with respect to r_m and rearrange terms to obtain

$$(14) \quad (\partial B^m / \partial r_m)(1/G(r_m)) \\ = U''_{r_m} \cdot (-X) \cdot [pF_K(K, X(K, p, r_m)) - c] \\ + U'_{r_m} \cdot pF_{KX}(K, X(K, p, r_m))(\partial X / \partial r_m).$$

The sign of (dK/dr_m) is generally ambiguous because the two terms on the right side of (14) have opposite signs, regardless of whether K and X are substitutes or complements. Thus, the effect of a change in the minimum price on the optimal level of capital is generally indeterminate.

Mean-Preserving Contraction with Maximum and Minimum Prices

A marginal increase in uncertainty, examined by Sandmo, corresponds to a "stretching" of the probability distribution around a constant mean" (p. 67). Eeckhoudt and Hansen noted that "the notion of a stretching of the probability distribution has some intuitive appeal, but it is hard to think of exogenous factors which would yield this specific change in the subjective expectations of the firm" (p. 1066). They suggested that

$$(18) \quad dA/dK = B(K, p, c, r_m, r_M) = U'_{r_m} \cdot [pF_K(K, X(K, p, r_m)) - c]G(r_m) \\ + \int_{r_m}^{r_M} U' \cdot [pF_K(K, X(K, p, r)) - c]dG(r) \\ + U'_{r_M} \cdot [pF_K(K, X(K, p, r_M)) - c](1 - G(r_M)) = 0.$$

a mean-preserving spread or contraction can be implemented through changes in minimum and maximum prices.⁵ Moreover, these price bounds are widely used in commodity price stabilization programs in the United States and the European Economic Community.

We first define a mean-preserving contraction in the input price r through maximum and minimum prices around a constant mean. Let the domain of the random input price be in the open interval (a, b) such that $G(a) = 0$ and $G(b) = 1$. Consider a binding minimum price r_m ($r_m > a$) and a maximum price r_M ($r_M < b$) which preserves the mean price $E(r)$. A mean-preserving contraction or "price squeeze" satisfies the condition,⁶

$$(15) \quad \int_a^b rg(r)dr = G(r_m)r_m + \int_{r_m}^{r_M} rg(r)dr \\ + (1 - G(r_M))r_M.$$

The required change in r_M following a change in r_m to maintain the same mean can be derived by totally differentiating (15) with respect to r_m and r_M ,

$$(16) \quad dr_M/dr_m = -G(r_m)/[1 - G(r_M)] \equiv -\Theta.$$

Next, consider the optimal choice of capital for a risk-averse firm facing a set of imposed maximum and minimum prices on the random input price r . The firm's problem is to choose K to maximize the expected utility,

$$(17) \quad A = U[\pi(K, p, r_m) - cK]G(r_m) \\ + \int_{r_m}^{r_M} U[\pi(K, p, r) - cK]dG(r) \\ + U[\pi(K, p, r_M) - cK](1 - G(r_M)).$$

The first-order condition is

One can verify that, at the optimum, the following conditions hold:

$$(19a) \quad pF_K(K, X(K, p, r_m)) > c \\ > pF_K(K, X(K, p, r_M))$$

if K and X are substitutes,

$$(19b) \quad pF_K(K, X(K, p, r_m)) < c \\ < pF_K(K, X(K, p, r_M))$$

if K and X are complements.

We now analyze the effect of a mean-preserving contraction through a change in the maximum and minimum prices on the optimal level of capital K^a of the competitive firm. Consider changes in r_m and r_M , holding $E(r)$ constant. Then at the optimum,

$$(\partial B / \partial K)dK + (\partial B / \partial r_m)dr_m + (\partial B / \partial r_M)dr_M = 0.$$

Because $(\partial B / \partial K) < 0$ by the second-order condition for optimal K , we observe that using (16),

$$\text{sign}(dK/dr_m)|_{dE(r)=0} \\ = \text{sign}\{(\partial B / \partial r_m) - (\partial B / \partial r_M)\Theta\}.$$

⁵ Obviously, price stabilization through changing minimum and maximum prices is a special case of mean-preserving contraction considered by Hartman (1976) and Wright (1984).

⁶ The effect of global change in the input price uncertainty can be obtained by setting r_m and r_M equal to the mean $E(r)$.

Recall that $(-\Theta)$ is the rate of change in r_M for a small increase in r_m to maintain the same mean. We evaluate $(\partial B/\partial r_m)$ and $(\partial B/\partial r_M)$, and obtain,

$$(20) \quad (\partial B/\partial r_m) - (\partial B/\partial r_M)\Theta \\ = U''_{r_m} \cdot (-X)[pF_K(K, X(K, p, r_m)) - c]G(r_m) \\ - U''_{r_M}(-X) \cdot [pF_K(K, X(K, p, r_M)) - c]G(r_m) \\ + [U'_{r_m} \cdot pF_{KX}(K, X(K, p, r_m))(\partial X/\partial r_m) - U'_{r_M} \\ \cdot pF_{KX}(K, X(K, p, r_M))(\partial X/\partial r_M)]G(r_m).$$

Using the results in (19a) and (19b), we can unambiguously determine the signs of the first two terms on the right side of (20). Both terms are negative (positive) if K and X are substitutes (complements). The third term can be written as

$$(21) \quad pF_{KX}(K, X(K, p, r_m))(\partial X/\partial r_m) \cdot [U'_{r_m} - U'_{r_M}]G(r_m) \\ + [pF_{KX}(K, X(K, p, r_m))(\partial X/\partial r_m) - pF_{KX}(K, X(K, p, r_M))(\partial X/\partial r_M)] \cdot U'_{r_M} \cdot G(r_m).$$

Because concavity of $U(\cdot)$ implies that U'_{r_m} is less than U'_{r_M} , the first term in (21) is negative (positive) if K and X are substitutes (complements). It can be shown that the second bracketed terms in (21) are positive (negative) if π_K is concave (convex) in r .⁷ Wright (1984) noted that the curvature of π_K with respect to r indicates how a change in K affects the slope of the variable input demand curve for X . Specifically,

$$\pi_{Krr} = \pi_{rrK} = -(\partial^2 X/\partial K \partial r).$$

If π_{Krr} is positive (negative), then the slope of the variable input demand curve for X becomes flatter (steeper) as K increases. This result is formally stated below.

PROPOSITION 1. *Assume that the competitive firm is risk averse. Then, (i) an increase in the maximum price r_M increases (decreases) the optimal level of capital K^a if K and X are substitutes (complements), but the effect of an increase in the minimum price r_m is ambiguous; and*

(ii) an MPC in r decreases (increases) the optimal level of capital K^a for a risk-averse competitive firm if K and X are substitutes (complements) and if the variable input demand curve becomes flatter (steeper) as K increases.

⁷ The second bracketed terms in (21) will be positive (negative) if π_K is concave (convex) in r . Observe that $\pi_K = pF_K(K, X(K, p, r))(\partial X/\partial r)$, which is positive (negative) if K and X are substitutes (complements). Furthermore, if π_K is concave in r , i.e., $\pi_{Krr} < 0$, then $pF_{KX}(K, X(K, p, r_m))(\partial X/\partial r_m)$ is greater than $pF_{KX}(K, X(K, p, r_M))(\partial X/\partial r_M)$ regardless of whether K and X are substitutes or complements. Thus, the second bracketed terms in (21) are positive. Alternatively, if π_K is convex in r , i.e., $\pi_{Krr} > 0$, then $pF_{KX}(K, X(K, p, r_m))(\partial X/\partial r_m)$ is less than $pF_{KX}(K, X(K, p, r_M))(\partial X/\partial r_M)$ regardless of whether K and X are substitutes or complements. Thus, the second bracketed terms in (21) are negative. Also note that an expression for π_{Krr} corresponds to equation (A.7) in Wright.

It can be shown that for a risk-neutral firm, if π_{Krr} is positive (negative) then an MPC in r decreases (increases) the optimal level of capital. For a risk-averse firm, however, in addition to the property of π_{Krr} complementarity and substitutability of K and X play an important role in determining the effect of an MPC on the optimal level of capital.

Expected Variable Input Demand and Output Supply

How does an MPC in the input price r affect the expected demand for the variable factor? An MPC

affects the expected variable input demand $EX(K^n, F, r)$ directly through the change in the price bounds and also indirectly via a change in the optimal level of capital, K^a . To investigate the total effect of an MPC, let $K^{a,1}$ and $K^{a,2}$ be the optimal levels of capital of the risk-averse firm before and after an MPC, and let $X(K^{a,1}, p, r^1)$ and $X(K^{a,2}, p, r^2)$ denote the variable input demands before and after the MPC, respectively. The direct effect depends on the curvature of the variable input demand curve. Specifically if the demand curve $X(K, p, r)$ is concave (convex) in r , then for a given level of $K^{a,1}$, $EX(K^{a,1}, p, r^2) > (<) EX(K^{a,1}, p, r^1)$, i.e., an MPC in r increases (decreases) the expected demand for the variable factor.⁸

The indirect effect depends on the response of the capital input to an MPC in r , and whether

⁸ Let $H(r)$ be the induced distribution of r by truncating $G(r)$ at two end points, r_m and r_M . Thus, $h(r) = g(r)$ for $r \in (r_m, r_M)$, $h(r_m) = G(r_m)$ and $h(r_M) = 1 - G(r_M)$. The expected variable input demand can be rewritten as $E[X(K, p, r)] = \int X dH(r; \alpha)$, where $H(r; \alpha)$ is the induced distribution of r and α is a shift parameter so that an increase in α represents an MPC in the distribution H and the range of the integration is over the loose interval $(0, \infty)$. For a given value of K , differentiate EX with respect to α and integrate the result by parts twice:

$$\int_0^\infty X dH_\alpha(r; \alpha) = - \int_0^\infty X_r G_\alpha(r; \alpha) dr \\ = \int_0^\infty X_{rr} \left[\int_0^\infty G_\alpha(s; \alpha) ds \right] dr,$$

where the subscript denotes partial derivative. Note that for an MPC,

$$\int_0^\infty H_\alpha(s; \alpha) ds \leq 0.$$

Thus $X_{rr} < 0$ implies that $\int_0^\infty X dH_\alpha(r; \alpha)$ is positive.

K and X are complements or substitutes. If π_{Krr} is negative and K and X are complements ($F_{KX} > 0$), then by part (ii) of proposition 1, an MPC increases the capital input ($K^{a,2} > K^{a,1}$). In this case, the indirect effect of an MPC increases expected variable input demand, i.e., $EX(K^{a,2}, p, r^2) > EX(K^{a,1}, p, r^2)$. Alternatively, if π_{Krr} is positive and K and X are substitutes ($F_{KX} < 0$), then an MPC decreases the capital input ($K^{a,2} < K^{a,1}$). In this case, the indirect effect increases the expected variable input demand, i.e., $EX(K^{a,2}, p, r^2) > EX(K^{a,1}, p, r^2)$. Thus, the indirect effect of an MPC increases the expected variable input demand if $\pi_{Krr} \cdot F_{KX}$ is negative. However, if $\pi_{Krr} \cdot F_{KX} > 0$, then K^a may increase or decrease, and the indirect effect is ambiguous. The total effect of an MPC in r on the expected variable factor demand for the risk-averse firm is summarized below.

PROPOSITION 2. *An MPC in r increases the expected variable input demand $EX(K^a, p, r)$ if $X_{rr} < 0$, $\pi_{Krr} \cdot F_{KX} < 0$.*

Next, consider the effect of an MPC in r on the expected output supply. The direct effect of an MPC in r on expected output depends on the curvature of the supply function $Q(K^a, p, r)$ in r . Specifically, if $Q(K^a, p, r)$ is concave (convex) in r , an MPC in r increases (decreases) expected output. The indirect effect depends on how an MPC affects the optimal level of K and whether K is a normal factor. Because K is assumed to be a normal input, if $\pi_{Krr} < 0$ and $F_{KX} > 0$, then an MPC increases K^a . This in turn shifts the supply schedule $Q(K^a, p, r)$ to the right and, hence, the indirect effect increases expected output. Alternatively, if $\pi_{Krr} > 0$ and $F_{KX} < 0$, then K^a decreases and, hence, the indirect effect decreases expected output. The total effect of an MPC in r on the expected output for the risk-averse firm is summarized below.

PROPOSITION 3. *An MPC in r increases expected output $EQ(K^a, p, r)$ if $Q_{rr} < 0$, $\pi_{Krr} < 0$ and $F_{KX} > 0$ but decreases expected output if $Q_{rr} > 0$, $\pi_{Krr} > 0$ and $F_{KX} < 0$.*

Thus, the effect of an MPC on the expected output of a risk-averse firm depends also on the complementarity or substitutability between K and X .

Concluding Comments

While the literature extensively analyzed the effects of output price stabilization policies on

supply responses, the effects of factor price stabilization on production decisions have received scant attention. Price stabilization policies are applied to primary commodities such as corn and wheat which are used as inputs in the food processing and livestock sectors. Price stabilization for these commodities is achieved by the use of maximum and minimum prices in the United States and the EEC. Specifically, in the United States, price support programs generally limit the movements of corn and wheat prices between the price floor (loan rate) and price ceiling (release price) through a buffer stock scheme. Similarly, prices are stabilized between intervention and target prices in the EEC.

This paper investigates how factor price stabilization, through changes in maximum and minimum prices, affects production decisions of risk-averse firms which use primary commodities as inputs. Following Turnovsky, we emphasize the ability of the firm to adjust its output after the variable input price is known. We have shown that an increase in the maximum price increases (decreases) the optimal level of capital according to whether capital and the variable input are substitutes (complements). On the other hand, the effect of an increase in the minimum price on the optimal level of capital is generally ambiguous. The effect of an MPC in r , which requires a decrease in the maximum price and an increase in the minimum price, on the optimal level of capital of a risk-averse firm depends, in addition to the relationship between capital and the viable input, upon the observable characteristics of the variable input demand curve, i.e., how its slope changes as K changes.

Interactions between Agricultural and Resource Policy: The Importance of Attitudes toward Risk

Howard D. Leathers and John C. Quiggin

Using a method proposed by Meyer for deriving comparative statics results in the presence of risk, this paper analyzes the effects of various agricultural and environmental policy alternatives on the choices of a risk-averse producer with a Just and Pope production function. Many commonly held beliefs about policy effects are not supported unambiguously by economic theory. For example, a tax on pesticides will not necessarily reduce pesticide use or average output, and a reduction in price of agricultural output will not necessarily lead to a reduction in use of water or agricultural chemicals.

Key words: agricultural policy, resource policy, risk.

Considerable attention has been given to the interactions between agricultural policy and environmental/resource policy (e.g., Just and Bockstael). To a great extent the policy interactions reflect the use in agricultural production of inputs, such as pesticides, fertilizer, and irrigation, that can affect environmental quality. An environmental program which reduced the use of pesticide, for example, would influence agricultural output and thereby influence the effectiveness of certain agricultural policies. Similarly, an agricultural program which increases crop production will influence fertilizer use and thereby influence the effectiveness of certain environmental policies.

This paper analyzes the effects of various agricultural and environmental policy alternatives on the choices of a risk-averse producer who uses inputs such as pesticides, chemical fertilizer, and irrigation. The analysis is based on comparative statics results for a risk-averse producer with a Just and Pope production function (1978, 1979), in which input choice can affect the mean and higher moments of output. This characteristic was designed to capture the production impacts of inputs like pesticides and fertilizer. Pesticides, for example, cushion the fall in yield that would occur during pest infestations, thus af-

fecting the variation of yield as well as average yield.

Some comparative statics results with a Just and Pope production function have been derived by Feder (1977). However, Feder does not derive all changes in output and input caused by policy-induced changes in parameters; thus, his paper is not a sufficient basis for drawing policy conclusions. What is more, despite its popularity, the usual Just and Pope production function is not an entirely satisfactory representation of an input such as pesticides.¹

The paper is organized as follows. The next section reviews the Just and Pope production function and the Meyer results for obtaining comparative statics under uncertainty. Comparative statics results then are derived for a Just and Pope production function, and the analysis is extended to the cases of truncated distributions and multiple inputs. Policy implications are considered in the concluding section.

Just and Pope Production Functions and the Meyer Results

The Just and Pope production function is $y = f(x) + h(x)\varepsilon$, where y is output, x is input, and ε is a random variable. Here f and h are assumed

Howard D. Leathers is an assistant professor, and John C. Quiggin is an associate professor, both in the Department of Agricultural and Resource Economics, University of Maryland.

¹ This point was made with unusual clarity by an anonymous reviewer, whose comments led to some of the extensions presented in the fourth section.

nonnegative. Further, ε takes the form $\varepsilon = \varepsilon^* + (\gamma) \cdot (\varepsilon^* - E(\varepsilon^*))$, where ε^* is a random variable with the same mean as ε and γ is a positive constant (Sandmo). Therefore, $E(\varepsilon^*) = E(\varepsilon) \equiv \mu_\varepsilon$, $\text{Var}(\varepsilon) = \gamma^2 \text{Var}(\varepsilon^*)$, and $\sigma_\varepsilon = \gamma \sigma_{\varepsilon^*}$, where σ_{ε^*} is the standard deviation of the random variable ε^* . This representation of ε allows a spread-preserving change in mean of ε to be indicated by a change in μ_ε , and a mean-preserving multiplicative spread of ε by a change in γ : $\partial \sigma_\varepsilon / \partial \gamma > 0$.

By assumption, increased input use increases average output at a decreasing rate: $f' + h'\mu_\varepsilon$

$$\begin{aligned} F_i(k) &\equiv \Pr(\pi_i < k) = \Pr(\varepsilon < [k + wx_i - pf(x_i)]/ph(x_i)) \\ &= \Pr(\varepsilon < \beta k / ph(x_i) + [wx_i - pf(x_i)]/ph(x_i) + \alpha / ph(x_i)) \\ &= \Pr(pf(x_i) + ph(x_i)\varepsilon - wx < \beta k + \alpha) = \Pr(\pi_j < \beta k + \alpha) \\ &= F_j(\beta k + \alpha). \end{aligned}$$

where $\beta = ph(x_i)/ph(x_i)$, and

$$\alpha = ph(x_i) \cdot [wx_i - pf(x_i)]/ph(x_i) - [wx_j - pf(x_j)]$$

> 0 , $f'' + h''\mu_\varepsilon < 0$. Some inputs (pesticides and irrigation) are risk reducing: $h' < 0$. Use of pesticide, for example, increases yield when a pest infestation occurs but does not affect yield when no infestation occurs. By eliminating the lower tail of the yield distribution, pesticide use will increase mean yield and reduce the variance of yield. Some inputs (fertilizer) are risk increasing: $h' > 0$. Use of fertilizer increases the probability of very high yields (for example, when rainfall is adequate and timely) but also increases the probability of low yields (for example, when rainfall is inadequate and chemical burning occurs). Thus, increasing fertilizer use increases both mean yield and yield variability.

A producer chooses x to maximize expected utility of income:

$$(1) \quad \max EU(\pi(x)),$$

where U is a continuously differentiable utility function defined on income or profits, π .

The comparative statics results in this paper are derived using the simplified procedure proposed by Meyer. This procedure does not require any additional assumptions about the form of the utility function or the distribution of the random variable, ε^* . The Meyer approach is valid whenever members of the choice set differ only by location and scale parameters. This section shows that the location and scale condition holds in the case of the Just and Pope production function and reviews some basic results from the Meyer paper.

Any level of the choice variable x , say x_i , cor-

responds to random variable π_i , where

$$\pi_i = pf(x_i) + ph(x_i)\varepsilon - wx_i.$$

Thus, the producer's problem is viewed as one of choosing an element of the set of random variables containing all the π_i 's as defined above.

Elements of this choice set differ only by location and scale (LS) parameters if $F_i(k) = F_j(\beta k + \alpha)$, where F_i and F_j are the cumulative density functions for random variables π_i and π_j , z is any value in the range of the *cdf*, and β and α are nonstochastic terms.

To see that this holds here:

This fact allows us to use the simplified comparative statics procedure proposed by Meyer. For the problem at hand, the solution to problem (1) above is equivalent to the solution to the problem:

$$(2) \quad \max_x V(\mu, \sigma),$$

where $\mu = pf(x) + ph(x)\mu_\varepsilon - wx$, and $\sigma = p \cdot h'(x) \cdot \sigma_\varepsilon = p \cdot h'(x) \cdot \gamma \cdot \sigma_{\varepsilon^*}$.

Meyer shows the following:

1. $V_\mu \geq 0$.
2. $V_\sigma < 0$ iff $U'' < 0$ (risk aversion).
3. $S(\mu, \sigma) \equiv -V_\sigma/V_\mu > 0$ under risk aversion.
4. If $U'' < 0$, then V is concave, so, $V_{\mu\mu} \leq 0$; $V_{\sigma\sigma} \leq 0$; and $V_{\mu\mu}V_{\sigma\sigma} - (V_{\mu\sigma})^2 \geq 0$, under risk aversion.
5. $S_\mu (<, =, >) 0$ under (decreasing, constant, increasing) absolute risk aversion (DARA, CARA, and IARA). In addition:
6. $S_\sigma \geq 0$ under DARA or CARA. (See appendix for proof.)

These results will be referred to in deriving comparative statics results in the next section.

These results can be represented using familiar graphs of indifference curves and feasible sets in (μ, σ) space, shown in figure 1.² $V(\mu, \sigma)$ is a representative indifference curve. Under risk aversion, V is upward sloping (property 3), and increases at an increasing rate (property 4).

² The graphical exposition was suggested by Kwan Choi, to whom we owe a debt of gratitude. Any errors are the responsibility of the authors.

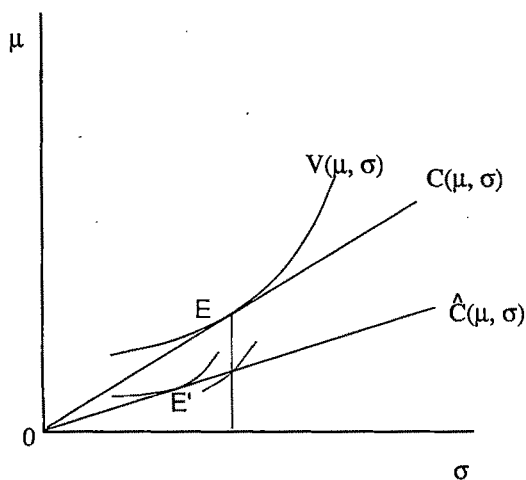

Figure 1. A graphical representation of comparative statics results

Property 5 states that, moving up along a vertical line, the indifference curves get steeper under IARA and flatter under DARA. (The DARA case is illustrated in fig. 1.) Property 6 states that moving to the right along a horizontal line, the indifference curves get steeper under DARA or CARA. The area under $C(\mu, \sigma)$ is the feasible set—the set of attainable combinations of

where

$$\mu = pf(x) + ph(x)\mu_e - wx, \text{ and}$$

$$\sigma = p \cdot h(x) \cdot \sigma_e = p \cdot h(x) \cdot \gamma \cdot \sigma_e^*.$$

One reassuringly unambiguous result from first-order conditions is

$$pf' + ph'\mu_e - w = Sph'\sigma_e^*.$$

Since $S > 0$ under risk aversion, the sign of this expression is the sign of h' , and the risk-averse producer will use more of the risk-reducing input, and less of a risk-increasing input, than will a risk-neutral producer, who sets the left-hand side equal to zero.

However, other comparative statics results are ambiguous. Comparative statics are derived from implicit differentiation of Φ . For any parameter α , $\partial x/\partial \alpha = -[\partial \Phi/\partial \alpha]/[\partial \Phi/\partial x]$. The sufficient condition for an interior optimum is that $\partial \Phi/\partial x < 0$. In the case of a risk-averse producer choosing a risk-increasing input (fertilizer), an interior solution is by no means assured. However, when the optimal choice is to use none of an input, this optimum will not be changed by small changes in parameters. Attention here is restricted to the case of interior solutions.

For interior solutions, the sign of $\partial x/\partial \alpha$ is the same as the sign of $\partial \Phi/\partial \alpha$.

$$(4a) \quad \partial \Phi/\partial w = -1 - ph'\gamma\sigma_e^* \cdot S_\mu \cdot (\partial \mu/\partial w) = -1 + ph'\gamma\sigma_e^* S_\mu x$$

$$\partial \Phi/\partial p = f' + h'\mu_e - Sh' - ph'\gamma\sigma_e^* S_\mu \cdot (\partial \mu/\partial p) - ph'\gamma\sigma_e^* S_\sigma \cdot (\partial \sigma/\partial p)$$

$$(4b) \quad = (w/p) - ph'\gamma\sigma_e^* \cdot [S_\mu \cdot (f + h\mu_e) + S_\sigma \cdot h\gamma\sigma_e^*]$$

$$(4c) \quad \partial \Phi/\partial \gamma = \left[-Sph'\sigma_e^* - ph'\gamma\sigma_e^* S_\sigma \cdot \frac{\partial \sigma}{\partial \gamma} \right] = -ph'\sigma_e^* [S + S_\sigma \gamma ph\sigma_e^*]$$

$$(4d) \quad \partial \Phi/\partial \mu_e = ph' - ph'S_\mu \cdot \frac{\partial \mu}{\partial \mu_e} = ph' [1 - S_\mu ph].$$

μ and σ . The shape of C is determined by the production function. As parameters change, the boundary of this set will change. These comparative statics are explored next.

Comparative Statics from a Just and Pope Production Function

The first-order condition associated with (2) is

$$(3) \quad V_\mu(\partial \mu/\partial x) + V_\sigma(\partial \sigma/\partial x) = 0, \text{ or} \\ (\partial \mu/\partial x) - S \cdot (\partial \sigma/\partial x) = 0; \text{ or} \\ \Phi = pf' + ph'\mu_e - w - S(\mu, \sigma)ph'\gamma\sigma_e^* = 0,$$

The comparative statics results are derived from (4) using results 1 through 6 in the above section. Comparative statics are summarized in the following propositions.

PROPOSITION 1. For a risk-averse producer and a risk-reducing input,

A. $\partial x/\partial w < 0$ under IARA, CARA (4A and result 5).

B. $\partial x/\partial p > 0$ under CARA (4B and result 5).

C. $\partial x/\partial \gamma > 0$ under DARA, CARA (4C and results 3, 6).

D. $\partial x/\partial \mu_e < 0$ under DARA, CARA (4D and result 5).

The results of proposition 1 broaden the findings of Feder with regard to pesticides. Result A confirms Feder's conclusion: "the impact of an increase in pesticide costs on pesticide dosage may be ambiguous . . . if absolute risk aversion is decreasing. . . . With constant absolute risk aversion, this ambiguity does not appear" (1979, p. 99). Here, we show that the result is also unambiguous under IARA.

The intuition behind this result can be understood by regarding each parameter change as having two effects: a direct effect and a wealth effect that operates by changing the farmer's attitude toward risk. Thus, an increase in the price of the input has the direct effect of causing the individual to buy less of the input, but the indirect effect is to reduce the individual's wealth. For a DARA individual, this reduction in wealth causes an increase in aversion to risk, which makes the individual demand more of a risk-reducing input. The balancing of these two effects creates ambiguities in the comparative statics results.

Result B shows that a similar ambiguity exists concerning the impact of an increase in output price on use of a risk-reducing input except under CARA. In order for this to be unambiguously positive, we need to have $[S_\mu(f + h\mu_e) + S_\sigma h\gamma\sigma^*] \geq 0$, which will happen if $S_\mu \geq 0$ and $S_\sigma \geq 0$. $S_\mu \geq 0$ requires IARA or CARA; $S_\sigma \geq 0$ requires DARA or CARA. The intuition here is more difficult. An increase in output price has three effects: First, it increases the expected marginal product, creating a tendency to increase input use. Second, the increase in price causes an increase in variability of revenue tending to make a producer restrict input use. As with output price risk (Sandmo, Ishii), the effect of the mean dominates the effect of variability for DARA and CARA producers. However, this is not enough to unambiguously sign the total effect. Third, the increase in price has a wealth effect, making producers more wealthy. This makes DARA producers less risk averse (encouraging less use of a risk-reducing input) and IARA producers more risk averse (encouraging more use of a risk-reducing input). Because CARA producers do not respond to a wealth effect, this third effect is irrelevant for them.

Result C states that an exogenous decrease in yield risk, holding expected yield constant, will lead to a decrease in use of risk-reducing inputs by DARA and CARA producers. The ambiguity here exists for IARA producers. This corresponds to the ambiguity for IARA producers

found in analyses of producers' response to a mean-preserving price stabilization scheme (Sandmo, Ishii).

Similarly, an exogenous decrease in μ_e , holding yield variance constant, will decrease the use of a risk-reducing input by DARA and CARA producers but not necessarily by IARA producers. This confirms Feder's result: "[Under DARA or CARA], an increase in the mean of [damage caused by a pest] will induce higher level of pesticide application" (1979, p. 99). To see that an increase in pest infestation corresponds to a decrease in μ_e , note that a drop in μ_e decreases expected yield but increases expected marginal effectiveness of input use.

PROPOSITION 2. *For a risk-averse producer and a risk-increasing input:*

A. $\partial x/\partial w < 0$ under DARA, CARA (4A and result 5)

B. $\partial x/\partial p$ is of indeterminate sign under any assumption.

C. $\partial x/\partial \gamma < 0$ under DARA, CARA (4C and results 3, 6).

D. $\partial x/\partial \mu_e > 0$ under DARA, CARA (4D and result 5).

Proposition 2 shows that ambiguities in comparative statics also exist for risk-increasing inputs. Result A shows that an increase in input price will unambiguously cause a decrease in use of risk-increasing inputs only if the producer is DARA or CARA. This is in contrast to the above result for risk-reducing inputs, where the effect was unambiguous only for IARA or CARA producers. The intuition is the same as in proposition 1. Here, the wealth effect of an input price increase makes DARA producers more risk averse and creates an additional tendency to reduce use of risk-increasing inputs.

The effect of a change in output price in the use of risk-increasing inputs cannot be determined under any assumption about attitudes toward risk. In order for this effect to be positive, it is sufficient that S_μ and S_σ be nonpositive. $S_\mu \leq 0$ under DARA, CARA, while S_σ can be nonpositive only under IARA. Note that the assumption of IARA is not sufficient to ensure that $S_\sigma \leq 0$. This fact precludes drawing unambiguous conclusions even for CARA, as in proposition 1.

An exogenous decrease in yield risk, holding mean yield constant, will increase use of a risk-increasing input by DARA and CARA producers. This differs from the result on risk-reducing inputs, where DARA and CARA producers used

less of the input in response to a mean-preserving spread of yield. An exogenous increase in mean yield, holding yield risk constant will increase use of a risk-increasing input by DARA and CARA producers. This result, too, differs from the analogous result in proposition 1, which says that DARA and CARA producers will respond to an increase in μ_e by reducing the amount of a risk-reducing input. For risk-increasing inputs, an increase in μ_e might be caused by a new seed variety, which increased expected yields, and also increased average marginal productivity of fertilizer.

These comparative statics results can be illustrated using figure 1. For example, an increase in w reduces the slope of C^3 if x is a risk increasing input ($h' > 0$). For CARA and DARA firms, indifference curves are more steeply sloped moving down a vertical line old tangency point; thus the new point of tangency must be one with lower μ and σ . This illustrates proposition 2A—an increase in w causes a decrease in use of risk-increasing inputs for DARA and CARA firms.

Model Extensions

The Just-Pope representation has a number of problems. In this section, some of the problems are identified and ways to modify the above model are suggested.

The Just and Pope production function is limited to a single input. Although in some contexts this feature could be rationalized in terms of a composite input, this approach is unattractive when the object is to analyze input demand response for a risk-reducing (or increasing) input such as irrigation or fertilizer.

The restriction may be relaxed in two ways. First, a vector z of "riskless" inputs can be added to the single risk-reducing (or increasing) input, leading to a production function of the form

$$(5a) \quad y = \phi(x, z) + h(x)\varepsilon.$$

The first-order condition on z is

$$(5b) \quad E[U'(p)(p\phi_z - w_z)] = 0,$$

where w_z is the wage rate for input z . Since the term $(p\phi_z - w_z)$ is nonstochastic, this condition can be satisfied only if $p\phi_z = w_z$. The marginal product ϕ_z depends on x but not on the stochastic term ε . Hence, it is possible to "nest"

the maximization problems, first choosing an optimal $z(x)$ satisfying $p\phi_z = w_z$, and then writing:

$$(5c) \quad f(x) = \phi(x, z(x)).$$

This approach yields the original Just-Pope representation. In order to deal with comparative static problems concerning a change in p , the slightly more complex form (5a) must be utilized. However, as long as the cross-derivative $\phi_{xz} \geq 0$, it is clear that the qualitative character of the results derived above will be unchanged.

The more general case is that of a multiple input production function in which all inputs affect risk, so that

$$(6) \quad y = f(x) + h(x)\varepsilon.$$

In the light of the analysis above, the optimization problem for (6) may be posed in the following two-stage fashion. First, for each value of σ , choose x to solve the problem

$$\max_x E\pi(x, p, w) \text{ such that } h(x)\sigma_\varepsilon = \sigma.$$

The solution to this problem determines the locus of available pairs (μ, σ) . The preference function $V(\mu, \sigma)$ may be used to determine the optimal (μ, σ) and hence the optimal x . The functional form (6) retains the linear separation, which ensures that the set of available distributions satisfies the LS condition; thus, the Meyer analysis may be applied. Input demand response is more complex, in this case, because both the preferred value of $h(x)$ and the least-cost x to yield this value must be determined. This problem will not be addressed in detail here.

The second major problem with the Just-Pope approach is that it yields a restrictive representation of risk and, particularly, of risk-reducing inputs such as pesticide. It is desirable to model these inputs as reducing losses in the worst states of the world and, hence, truncating (or, more precisely, winsorizing) the bottom tail of the distribution of outcomes. This possibility cannot be modeled in the Just-Pope framework, nor do the associated distributions satisfy the location and scale (LS) condition proposed by Meyer.

However, a number of studies (Quiggin and Anderson, Eeckhoudt and Hansen, Meyer and Ormiston 1983) have shown that risk reductions involving truncation of the bottom tail of a distribution have tractable comparative static properties. More recently, Quiggin (1986) and Meyer and Ormiston (1989) have studied a broad class of changes in risk which includes truncations and

³ The slope of C is $[\partial\mu/\partial x]/[\partial\sigma/\partial x] = (pf' + ph'\mu_e - w)/ph'\gamma\sigma_e^*$.

multiplicative spreads as special cases. Quiggin refers to such changes as monotone spreads.

The concept is best modeled by considering a random variable as a mapping g from a state space $[0, 1]$ to the outcome space \mathcal{R} such that $\omega_1 > \omega_2 \Rightarrow g(\omega_1) \geq g(\omega_2)$. Such a mapping may be regarded as the inverse of the cumulative distribution function for a continuously distributed random variable. Two variables g_1, g_2 are related by a monotone spread if $E[g_1] = E[g_2]$ and $g_1(\omega) - g_2(\omega)$ is a monotone increasing function of ω . Thus, in moving from g_1 to g_2 , the bad states get worse and the good states get better, or there is more weight in the tails of the distribution. Special cases in which two variables differ only by mean and a monotone spread include the case where g_1 is a mean-preserving multiplicative spread of g_2 (as represented by an increase in γ in the previous section), and the case where g_1 is a truncation of g_2 .

The analysis of the previous section may now be extended to cover production functions of the form

$$(7) \quad y_i = f(x_i, z_i) + \lambda(x_i)h(x^0, \omega) + (1 - \lambda(x_i))h(x^*, \omega),$$

where for two levels of input use, x^0 and x^* , the random variables $h(x^0, \omega)$ and $h(x^*, \omega)$ differ by a monotone spread, with common expected value \bar{h} .⁴

This formulation is sufficiently flexible to provide a plausible model of risk response for irrigation, fertilizer, and pesticide. To illustrate, define states of the world as the level of pest infestation, where a low state corresponds to high infestation; let x^0 represent no pesticide use, and x^* represent the level of pesticide use which eliminates pests all levels of infestation. Mapped against states, $h(x^*)$ is a horizontal line. Combined with $f(x^*)$, which is constant for all states by assumption, this gives us a constant $y(x^*)$. Mapped against states of the world, output $y(x^0)$ starts low, increases until it reaches a maximum in the state at which infestation is inconsequential, and then turns horizontal. Linear combinations of $h(x^0)$ and $h(x^*)$ all turn horizontal at the same (zero infestation) state.

Quiggin (1990b) shows that the Meyer approach can be applied to analyze comparative statics when the production function takes the form of (7). The properties of $V(\mu, \sigma)$ derived by Meyer for the LS case generalize to $V(\mu, \lambda)$.

Furthermore, since λ is linearly related to the variance and standard deviation, these properties carry over to $V(\mu, \sigma)$.

In the (7) representation, $\mu = pf(x_i, z_i) + p\bar{h} - wx - w_z \cdot z_i$, and $\sigma^2 = \lambda(x_i)\sigma_0^2 + (1 - \lambda(x_i))\sigma_*^2$, where σ_0^2 and σ_*^2 are the second central moments of the random variables $h(x^0, \omega)$ and $h(x^*, \omega)$, respectively.⁵ A change in σ_0^2 can be interpreted as a change in income variability attributable to crop insurance or any other exogenous change in variation of outcomes.

Finally, the Just-Pope and Meyer analyses have been confined to expected utility maximizers. The development of more general models of choice under uncertainty (Machina, Quiggin 1982) suggests that this is an unnecessary restriction. Quiggin (1990a) shows that the main EU comparative static results for monotone spreads carry over to the more general rank-dependent expected utility model. Quiggin (1990b) examines the relationship between preferences of the form $V(\mu, \sigma)$ and the general smooth preferences model of Machina.

Policy Implications

Although existing literature contains some of these comparative statics results, policy implications of the results have not been well developed. Many commonly held beliefs about policy effects, especially interactions between agricultural and resource policy, are not supported unambiguously by economic theory. Rather, they rest on presumptive answers to empirical questions concerning individual producer's attitudes toward risk.

In particular, the above analysis of comparative statics shows the following.

(a) A tax on pesticides will not cause all risk-averse farmers to use less pesticides, nor will it necessarily result in lower average output.

(b) A subsidy on water use will not cause all risk-averse farmers to increase water use or expected output.

Use of a risk-reducing input decreases as input price increases under the assumptions of IARA or CARA; but under the more usual assumption of DARA, an increase in input price could cause increased input use. Therefore, the standard assumptions on risk aversion are not sufficient to conclude that a water subsidy, or the failure of pesticide prices to reflect true so-

⁴ The assumption that $h(x^0, \omega)$ and $h(x^*, \omega)$ have the same expected value does not imply that expected output is the same for x^0 and x^* , since $f(x^0)$ and $f(x^*)$ can differ.

⁵ This expression for variance follows from the assumption that $h(x^0)$ and $h(x^*)$ are related by a monotone spread.

cial costs, causes agricultural pollution or creates a burden on agricultural price support programs by boosting output.

In addition, these results call into question the efficacy of Pigouvian taxes in controlling pollution derived from sources such as pesticides and irrigation. Internalizing externalities through a Pigouvian tax is straightforward when risk is not present (or when producers are risk neutral). When producers are risk averse, the tax will not only change w but will also change S in the first-order condition (3). In the case of a DARA producer, such a tax may have the perverse effect of causing input use to move farther away from the social optimum.

(c) A reduction in prices received by farmers will not necessarily lead to a reduction in use of water or agricultural chemicals.

This "expected" response holds unambiguously only for risk-reducing inputs used by CARA producers. Thus, a drop in the price received by farmers may not result in environmental improvement attributable to a decrease in use of environmentally deleterious inputs.

This result calls into question the belief that agricultural price support programs are an important cause of agricultural pollution. The theoretical results do not contradict this view, but neither do they support it. The question can only be resolved by empirical study.

(d) Introduction of a more pest resistant (or more drought resistant) seed variety, which reduces risk (σ_e) without affecting the mean of the distribution, will not necessarily result in a decline in use of agricultural chemicals.

DARA or CARA farmers will reduce use of water and pesticides but will not necessarily reduce fertilizer use. These results also hold for any other methods of reducing yield variability such as improved cultivation methods.

(e) Use of new seed varieties or production methods which decrease μ_e without affecting the variance of the distribution of yield will cause DARA and CARA farmers to use less pesticide and water but more fertilizer.

Conclusions

These results illustrate the difficulty of deriving policy effects for a risk-averse producer with a Just and Pope production function. At the extreme, theory yields no clear prediction of the effect of a change in output price on fertilizer (or other risk-increasing inputs). In order to get unambiguous and "normal" (i.e., usual, com-

monly expected) comparative statics results in every other case, it is necessary to assume constant absolute risk aversion. If one assumes decreasing absolute risk aversion, one must accept ambiguity in the impact of output and input price changes on risk-reducing inputs such as pesticides and irrigation or impose additional restrictions on risk attitudes.

In addition, exogenous changes in mean and variance of yield have opposing effects on risk-reducing and risk-increasing inputs. For example, an exogenous reduction in yield variation decreases use of pesticides but increases use of fertilizer. Thus, the overall impact of such a change on environmental damage caused by agricultural chemicals cannot be determined by theory alone.

This example illustrates the analytical difficulty highlighted by this paper: for this class of producer problems, conclusions about policy effects and prescriptions for optimal incentives cannot be based on theory alone. Rather, the analysis requires an empirical knowledge of the production function, the environmental impacts of input use, the risk attitudes of producers (the shape of each producer's utility function). Furthermore, the knowledge about the "average" attitude toward risk is not sufficient. Detailed knowledge is needed about the distribution of attitudes toward risk among farmers (Antle): how many farmers are DARA? how many are IARA? how many are "extremely" DARA? and how many are "only slightly" DARA?

In the absence of this empirical knowledge, descriptions of policy effects and interactions between agricultural and resource policy are problematic. Economic theory does not support (or contradict) judgments such as, "Price support programs cause increased agricultural pollution," or "Pollution taxes will reduce agricultural output," or "The environment would be improved by finding means other than pesticides or irrigation of reducing yield risk." This paper sounds a cautionary note to policy makers and analysts.

Appendix

Proof that $S_\sigma \geq 0$ under DARA or CARA

By result 5 above, the assumption of CARA or DARA implies $S_\mu \leq 0$. But $S_\mu = 1/V_\mu [-V_{\sigma\mu} + (V_\sigma/V_\mu)V_{\mu\mu}]$. Therefore, $[-V_{\sigma\mu} + (V_\sigma/V_\mu)V_{\mu\mu}] \leq 0$, or $F_{\sigma\mu} \geq V_\sigma/V_\mu V_{\mu\mu} \geq 0$ by results 3 and 4. Two conclusions follow from this: (A1) $V_{\sigma\mu} \geq 0$; and (A2) $V_{\sigma\mu}/V_{\mu\mu} \leq V_\sigma/V_\mu$. By result 4 (concavity of V), $V_{\sigma\sigma}V_{\mu\mu} - (V_{\sigma\mu})^2 \geq 0$, or using (A1), $V_{\sigma\sigma}/V_{\mu\mu} \leq V_{\sigma\mu}/V_\mu$. Combining this with (A2), we have $V_{\sigma\sigma}/V_{\sigma\mu} \leq V_\sigma/V_\mu$. This is sufficient to sign S_σ since $S_\sigma = 1/V_\mu [-V_{\sigma\sigma} + (V_\sigma/V_\mu)V_{\mu\sigma}]$

Joint Risk Preference-Technology Estimation with a Primal System

H. Alan Love and Steven T. Buccola

Applied studies of the firm in a risky environment have concentrated either on the firm's technology or on its risk preferences. These models result in generally inconsistent and inefficient parameter estimates. A primal model is proposed which allows a firm's preferences and technology to be estimated jointly in the presence of risk. The model is applied to Iowa corn production and estimated technology parameters are compared with those from other approaches. Modest risk aversion leads to inelastic (even backbending) per-acre supplies and input demands. Yield heteroskedasticity in inputs leads to supply heteroskedasticity in prices, especially for risk-neutral firms.

Key words: heteroskedasticity, input demands, production function, risk aversion, yields.

Econometric supply analysis has paid increasing attention to the relationship between a firm's price responses and its technology. Duality theorems, in particular, may allow one to derive mutually consistent supplies, input demands, and technology from a single cost or profit function. Unfortunately, risk and risk aversion greatly complicate the task of developing a linkage between economic choice and observed technology. Production relations must be expanded to include inputs' effects on yield variability. Dual approaches in such a context have proven troublesome because restrictions on the firm's expected utility function generally involve information about preferences, which are unknown (Pope 1982b). Attention, therefore, has turned to primal models of positive economic behavior under risk.

In the present paper, we consider alternative primal risk models which permit technology estimation only or permit input demand estimation given a technology or preference structure. Primal approaches presently in use are shown to have a number of correctable failings. Those focusing on technology alone have improperly assumed that inputs are exogenous, while those focusing on input demands have failed to estimate preference and technology parameters in a

mutually consistent manner. A model is proposed and tested which corrects these shortcomings and which provides a basis for consistent and efficient estimation of farm behavior under risk.

The paper begins with a brief review of production function and input demand models in a risky environment. Attention then is restricted to technologies in which marginal yield moments may be independent of one another. We explore implications of this technology class for input endogeneity and for joint inference of preferences and technology. Applications are provided to Iowa corn production, and our estimates are compared with those in earlier models.

Earlier Literature

Estimation of stochastic production functions received a boost when, following Harvey, Just and Pope (1979) showed that standard heteroskedasticity correction methods may be used to draw inferences about input-risk relationships. They assumed a normal yield distribution and allowed independence between an input's effects on yield risk and its effects on yield mean. The procedure involved estimating the mean portion of the production surface, fitting the risk portion through a regression on residuals, then improving efficiency of the mean estimates through Aitken-type weighting. Nelson and Preckel instead used maximum-likelihood meth-

The authors wish to thank David Birkes, Statistics Department, Oregon State University, for helpful comments and Heung-Dong Lee for extensive computer assistance.

ods to estimate an input's effects on the parameters of a beta yield distribution, which in turn affect the beta's mean, variance, and higher moments. Although moments of the beta distribution are not independent of one another, the model has sufficient flexibility to allow an input to increase yield mean but reduce yield variance.

Studies under risk which allow input use to respond optimally to prices generally have separated technology estimation from preference estimation. Prior estimates of technology parameters usually are imposed on input demands, leaving only risk preference terms to be estimated (Pope 1982a). A mathematical programming approach of this sort is to find optimal input allocations corresponding to alternative risk aversion levels, then to choose the risk-aversion-level-minimizing the distance between actual and optimal input rates (Wiens, Paris, Brink and McCarl).

In an alternative approach, Antle substituted prior parameter estimates of his moment-based stochastic production function into a set of input demands and used the constrained demands to fit parameters of the distribution of risk attitudes. Allowance for independence of marginal yield moments in Just and Pope's model is preserved, although the yield distribution may be nonnormal. In contrast, Loehman and Vandever have shown that an interactive biological growth model requires marginal mean and marginal variance of yield to be interdependent. They use prior estimates of the production function to simulate a parameter partially reflecting risk preference. Unfortunately, this parameter also reflects the probability moments of profit.

Separating preference from technology estimation in these ways potentially introduces both inconsistency and inefficiency. Technology parameters derived solely from production functions are inconsistent if input uses are endogenous and correlated with error terms (Pope 1982b, pp. 346-47). Whenever technology estimates are in fact inconsistent, preferences estimated conditionally on such parameters are inconsistent as well. Functional separation also fails to exploit cross-equation restrictions and error correlations that might improve efficiency.

Issues in Joint Estimation

Prospects for joint primal estimation of technology and preferences are influenced by the interdependence of marginal yield moments and

by the form of the utility function and yield distribution. For instance, interdependent marginal yield moments, as in Loehman and Vandever, imply the general production function form

$$(1) \quad Y = g(X)i(W, u),$$

where g and i are functions, Y is per-acre output, X is a vector of nonstochastic inputs, W is a vector of stochastic inputs such as rainfall, and u is a random error. A number of authors have argued for such a multiplicative model (Newbery and Stiglitz, pp. 304-5). Just and Pope's criticism of (1) is that an input's marginal effect on variance is a function of its marginal effect on mean. In addition, i must have positive skew in order to avoid possibilities of negative yields. An indeterminately large number of marginal yield moments thus enter the input demands, and joint preference-technology estimation becomes difficult.

Maintaining independence between marginal mean and variance implies

$$(2) \quad Y = f_1(X) + f_2(W) + h(X)\epsilon,$$

where $\epsilon \sim N(0, 1)$. Stochastic and nonstochastic inputs interact to affect yield's variance but not its mean. Prior to W 's occurrence, (2) has the Just-Pope form

$$(2') \quad Y = f(X) + h(X)\epsilon,$$

in which $E(Y) = f(X) = f_1(X) + E[f_2(W)]$. Despite its inconsistency with dynamic growth models and skewed yield distributions, this form is popular and holds the best potential for mutual inference of preferences and technology. We therefore concentrate on Just-Pope form (2') and, to permit tractable results, assume negative exponential utility $U(\pi) = -\exp(-\lambda\pi)$, where π is net return and λ is absolute risk aversion. Comparative statics of (2') in conjunction with nonincreasing risk aversion have been investigated by Pope and Kramer. Babcock, Chalfant, and Colander used a moment-generating function to derive specific input demands for the case of (2') and exponential utility.

Optimality Conditions

Optimal input levels for producers facing (2') are found by solving the primal problem,

$$(3) \quad \begin{aligned} \underset{x}{\text{Max}} \quad & E[U(\pi)] \\ & = \underset{x}{\text{Max}} EU[Pf(X) + Ph(X) - r'X]. \end{aligned}$$

Here P and r are (assumed known) output price and input price vector, respectively. To minimize the number of estimable parameters, we employ Cobb-Douglas forms of f and h , which in a two-variable-input case reduce (2') to

$$(4) \quad Y = AX_1^{a_1}X_2^{a_2} + BX_1^{b_1}X_2^{b_2}\epsilon,$$

with A, a_1, a_2, B, b_1, b_2 as parameters. Substituting (4) into (3), deriving first-order conditions, and using $U'(\pi)$ to denote (random) marginal utility, gives

$$(5) \quad \begin{aligned} E\{U'(\pi)[PAa_1X_1^{a_1-1}X_2^{a_2} + PBb_1X_1^{b_1-1}X_2^{b_2}\epsilon - r_1]\} &= 0, \\ E\{U'(\pi)[PAa_2X_1^{a_1}X_2^{a_2-1} + PBb_2X_1^{b_1}X_2^{b_2-1}\epsilon - r_2]\} &= 0. \end{aligned}$$

Taking expectations and dividing by $E[U'(\pi)]$ equates certainty equivalents of value marginal products with their corresponding input prices:

$$(6) \quad \begin{aligned} PAa_1X_1^{a_1-1}X_2^{a_2} + PBb_1X_1^{b_1-1}X_2^{b_2}t &= r_1, \\ PAa_2X_1^{a_1}X_2^{a_2-1} + PBb_2X_1^{b_1}X_2^{b_2-1}t &= r_2, \end{aligned}$$

where $t = E[U'(\pi)\epsilon]/E[U'(\pi)]$.

Parameter t is a function of both risk and risk aversion. If profit is expressed as $\pi = \mu + \sigma\epsilon$, in which μ is profit's mean and σ is its standard deviation, then t 's denominator is $E[U'(\pi)] = \lambda E[\exp(-\lambda\pi)] = \lambda E[\exp(-\lambda\mu - \lambda\sigma\epsilon)]$, that is λ times the expectation of a lognormally distributed variate with parameters $-\lambda\mu, \lambda^2\sigma^2$. The latter expectation is just $E[\exp(-\lambda\mu - \lambda\sigma\epsilon)] = \exp(-\lambda\mu + \lambda^2\sigma^2/2)$ (Johnson and Kotz). In like manner, t 's numerator becomes $E[U'(\pi)\epsilon] = \lambda E[\exp(-\lambda\mu - \lambda\sigma\epsilon)\epsilon] = [\lambda \exp(-\lambda\mu)] E[\exp(-\lambda\sigma\epsilon)\epsilon] = [\lambda \exp(-\lambda\mu)][-\lambda\sigma \exp(\lambda^2\sigma^2/2)] = -\lambda^2\sigma \exp(-\lambda\mu + \lambda^2\sigma^2/2)$.¹ Dividing numerator by denominator gives $t = E[U'(\pi)\epsilon]/E[U'(\pi)] = -\lambda\sigma$. The appearance of absolute risk aversion parameter λ in (6) only as a multiple of profit risk σ implies the two terms never can be separately identified in the input demands without introducing information from production function (4).

From (2'), (3), and (4), profit standard deviation $\sigma = P[\text{Var}(Y)]^{1/2} = PBX_1^{b_1}X_2^{b_2}$. Substituting the latter and $t = -\lambda\sigma$ into (6) and combining terms results in

$$(6'a) \quad PAa_1X_1^{a_1-1}X_2^{a_2} - P^2\lambda B^2b_1X_1^{2b_1-1}X_2^{2b_2} = r_1,$$

$$(6'b) \quad PAa_2X_1^{a_1}X_2^{a_2-1} - P^2\lambda B^2b_2X_1^{2b_1}X_2^{2b_2-1} = r_2.$$

Equations (6') are a specialization of Pope and Kramer's (p. 492) first-order conditions and differ from the Babcock-Chalfant-Collender input demands only in suppressing acreage terms. Inasmuch as $\lambda\sigma^2/2 = P^2\lambda B^2b_1X_1^{2b_1-1}X_2^{2b_2}/2$ is the producer's risk premium (RP), the marginal risk premium (MRP) with respect to the first input (MRP_1) is $\delta RP/\delta X_1 = P^2\lambda B^2b_1X_1^{2b_1-1}X_2^{2b_2}$, precisely the second right-hand side term in (6'a). MRP_2 is similarly given in (6'b). Pope and Kramer, and MacMinn and Holtmann, show that a

risk averter's optimal use of both inputs exceeds (falls short of) that in the riskless or risk-neutral case if the inputs are complementary and if $\delta h/\delta X_1, \delta h/\delta X_2 < 0 (> 0)$. In (4), these conditions are satisfied if $b_1, b_2 < 0 (> 0)$, that is, if yield is heteroskedastic such that yield variance decreases (increases) as inputs increase. Clearly, input demands need not shift parallel when λ changes; in fact, the demands may become positively sloped if risk aversion is high enough (Pope and Kramer, pp. 495-96).

Input Demand-Production System

All the parameters in (6') are in principle separately identifiable. Feasibility of estimating any parameter, including product λB^2 , on the basis of (6') alone depends on the associated demand error structure. Unfortunately, production function (4) provides no information about this structure. One approach is to solve for the input demands, then add an error to each in order to represent farmers' random deviations in identifying the true optimum. However, closed-form expressions for the optimal inputs do not exist. Solving (6') as far as possible for the optimal variable factors gives

$$(7) \quad X_1 = [r_1/(PAa_1X_2^{a_2} - P^2\lambda B^2b_1X_1^{2b_1-a_1}X_2^{2b_2})]^{1/(a_1-1)},$$

$$X_2 = [r_2/(PAa_2X_1^{a_1} - P^2\lambda B^2b_2X_1^{2b_1}X_2^{2b_2-a_2})]^{1/(a_2-1)},$$

so that optimal factors can only be determined simultaneously. Full information about a factor's optimum cannot be determined from price levels.

Simultaneity in (7) ensures that the error in each equation is generally correlated with all input choices even if optimization errors are spec-

¹ $E[\exp(-\lambda\sigma\epsilon)\epsilon] = -\lambda\sigma \exp(\lambda^2\sigma^2/2)$ can be proven by noting that the moment generating function of ϵ is $m(-\lambda\sigma) = E[\exp(-\lambda\sigma\epsilon)] = \exp(\lambda^2\sigma^2/2)$. Differentiating with respect to $-\lambda\sigma$ gives $m'(-\lambda\sigma) = E[\exp(-\lambda\sigma\epsilon)\epsilon] = -\lambda\sigma \exp(\lambda^2\sigma^2/2)$.

ified additively. As an alternative to additive errors, suppose that optimization mistakes occur in the form of random failure to satisfy first-order conditions (6'). Assuming choices are optimal on average, errors v_1, v_2 are added to (6'a) and (6'b) such that $E(v_1) = E(v_2) = 0$ and $\text{Var}(v_1) = S_1^2, \text{Var}(v_2) = S_2^2$.

Estimating production function (4) jointly with demand system (6') has several advantages. First, the two equation sets contain common parameters, so joint estimation with cross-equation restrictions can improve estimation efficiency compared to the use of (6') alone. Second, considering contemporaneous error correlations between the equation sets also can improve efficiency. Third, including (4) is necessary—and sufficient—for separately identifying absolute risk aversion λ and risk coefficient B^2 in (6').

To make clear how (4) may be used for these purposes, observe that the heteroskedasticity in its error can be removed by dividing each term by $X_1^{b_1} X_2^{b_2}$. The result is

$$(4') \quad YX_1^{-b_1} X_2^{-b_2} - AX_1^{a_1-b_1} X_2^{a_2-b_2} = B\epsilon,$$

with homoskedastic error $B\epsilon \sim N(0, B^2)$. Equations (4') and (6') now may be fitted jointly once a covariance structure for residuals $v_1, v_2, B\epsilon$ has been specified. Substituting into (4') consistent estimates of A, a_i, b_i that were derived from simultaneously fitting (4') and (6') gives $B\epsilon^*$ a consistent estimate of the production error vector. Log absolute value of $B\epsilon^*$ is $\ln|B\epsilon^*| = \ln B + \ln|\epsilon^*|$, the expectation of which is $\ln B + E \ln|\epsilon^*| = \ln B - 0.6352$ (Buccola and McCarl, p. 734). Adding 0.6352 and exponentiating gives a consistent estimate of B , which when squared and divided into the consistent estimate of λB^2 from (4') and (6') gives a consistent estimate of λ .

Inasmuch as inputs X in (4') are endogenous, fitting (4') along with (6') equivalently estimates the risk-averse firm's per-acre supply (yield) function

$$(8) \quad Y^* = f(X^*) + h(X^*)\epsilon,$$

where X^* is the vector of optimal input levels. Since, through (6'), X^* depends on prices P and r , supply must be heteroskedastic in the prices whenever yield is heteroskedastic in inputs.

Estimation Procedures

We here fit an extension of system (4'), (6') to corn-soybean farm data in Iowa. Resulting pro-

duction function estimates are compared with (a) those derived with the method of Just and Pope and (b) those estimated by Nelson and Preckel with the conditional beta distribution. Hausman's specification test is used to check for independence between input use and stochastic production error in the Just-Pope model. We jointly estimate the aggregate risk aversion parameters, contrast risk-averse with risk-neutral supplies and input demands, and discuss implications for supply heteroskedasticity.

The yield and input data are taken from Nelson and Preckel. They consist of farm-level information on per-acre corn yield; nitrogen, phosphorus, and potassium application; soil slope and clay content; and two dummy variables indicating, respectively, whether a legume preceded the corn crop by one or two years. Data were drawn from Linn ($n = 103$), Muscatine ($n = 55$) and Fayette ($n = 106$) Counties, Iowa, from 1954 through 1969.² Observations on a given farm are included only for years in which corn was grown. Because some farms grew corn sporadically during the study period, cross-farm differences in parameters or error variances cannot be adequately considered.

Substantial changes in both real prices and farm input proportions occurred during 1964–69, so it is a suitable period for testing hypotheses about price-input relations. Iowa input prices were taken from annual issues of U.S. Department of Agriculture's *Agricultural Prices and Agricultural Resources: Situation and Outlook Report*. Corn price was the average of high and low March closing prices of the Chicago corn futures contract maturing the following September. All prices were deflated with the Consumer Price Index (CPI).

Of the inputs for which data were available, only nitrogen, phosphorus, and potassium are purchasable in the medium run. Hence, equations (6) were extended to a system of three input demands. Soil slope and clay and the two dummy variables were included as exogenous factors in each equation, along with output and input market prices P, r . This extended version of (4'), (6') was estimated with nonlinear 3SLS combining the indicated cross-equation restrictions on parameters and holding λB^2 fixed at trial

² The data sets, collected by the Iowa Agricultural Experiment Station, are described in more detail in Nelson and Preckel. We wish to thank Carl Nelson for kindly furnishing them to us. Original data included soil type, insecticide use, and planting date. However, because many observations on these variables were missing, they could not be employed effectively in either the Nelson-Preckel study or our own.

values (Hall, Schnake, and Cummins). Instrumental variables employed in the first nonlinear three-stage least squares (NL3SLS) estimation stage at each trial value included all the exogenous variables plus soybean futures prices, which should be correlated with corn profitability and input usage but unrelated to individual farms' error terms.

A grid search, finally, was conducted on alternative λB^2 levels and the parameter set selected which minimized system sum square errors. Substituting optimal A , a_i , and b_i estimates back into (4') gave consistent estimates of $|B\epsilon|$, the adjusted mean log of which provided a consistent estimate of B and, through the NL3SLS estimate of λB^2 , a consistent estimate of λ . The NL3SLS estimator provides, in addition, consistent estimates of all the other parameters regardless of the underlying distribution of random errors v_1, v_2 (Amemiya, Gallant, Jorgenson and Laffont). Our grid search on λB^2 implies that the usually estimated standard errors are consistent conditional on the optimized λB^2 value.

Just-Pope-type estimates of (4) were derived by applying nonlinear least squares (NLS) to obtain stage 1 estimates of A and the a_i 's. Logs of absolute values of the residuals $u = BX_1^{b_1}X_2^{b_2}$ then were regressed against $\ln|BX_1^{b_1}X_2^{b_2} \dots \epsilon|$ to derive stage 1 estimates of B and the b_i 's. A stage 2 estimate of A and the a_i 's was obtained by applying NLS to the weighted regression (4') and a stage 2 estimate of B and the b_i 's was derived by repeating the log linear regression on residuals.³ A Just-Pope-type routine provides not only a point of comparison for the NL3SLS system estimates but a useful set of starting values for these estimates as well.

If, as (6') and (7) imply, inputs X are endogenous, they should be correlated with error term ϵ . The Just-Pope parameter estimates are then inconsistent (Just and Pope 1978, pp. 75–77). On the other hand, stochastic dependence may be so small that insignificant bias results. To implement the Hausman test of the null hypothesis, $H_0: X$ independent of ϵ in (4'), we construct two sets of estimates of the technology parameters: (a) the Just-Pope ($\hat{\beta}_o$), which is consistent, asymptotically normal, and asymptotically efficient when H_0 is true but inconsistent when H_0 is false; and (b) a nonlinear two-stage least squares (2SLS) version of the Just-Pope ($\hat{\beta}_a$),

which is asymptotically inefficient if H_0 is true and consistent and asymptotically normal whether it is true or false (Sargan, pp. 54–60; White).⁴ The appropriate test statistic is asymptotically chi-square with degrees of freedom equal to the number of elements in $(\hat{\beta}_a - \hat{\beta}_o)$ (Hausman, p. 1263). It was computed for each of the three Iowa counties, focusing only on yield-mean effects $f(X)$ because consistent estimates of the corresponding asymptotic covariance matrices $\hat{V}(\beta_o)$, $\hat{V}(\beta_a)$ are readily available.

Results

Results of the system estimates for Linn County are shown in the right column of table 1, alongside the Nelson-Preckel (pp. 375–76) and Just-Pope-type estimates in the left and center columns. (Muscatine and Fayette County results are available on request.) Dummies signifying previous legume crops were not significant in any of the regressions and were dropped. A wide range of values for λB^2 was tried for each county; in all cases, the optimal values fell in the positive range. NL3SLS estimates of technology parameters A , a_i , and b_i were only modestly sensitive to parameterized λB^2 levels in the neighborhood of their optima. Primal system t -values given in parenthesis in table 1 are conditional on the λB^2 chosen. Bracketed t -values are derived from estimates of the corresponding unconditional standard errors.⁵

Parameter Estimates

System estimates of the inputs' yield mean effects were fairly close to the Just-Pope (JP) estimates and in absolute value somewhat below the Nelson-Preckel (NP) figures. For example, whereas NP estimate that a 10% increase in potassium application in Linn County increased mean corn yield by 13%, the primal system and Just-Pope models show mean yield rising by only 3% and 5%, respectively. Phosphorus' curious negative effect on mean yield in NP's Linn

³ With small samples, this last log linear regression likely improves bias in B estimates and efficiency in a_i estimates (Buccola and McCarl, pp. 735–37). $\ln(B)$ also was adjusted by +0.6352 to account for residual asymptotic bias resulting from the fact that $E|\epsilon| = -0.6352$ in each log linear regression.

⁴ Estimator $\hat{\beta}_a$ is developed identically to $\hat{\beta}_o$ except that inputs X specified at each Just-Pope stage are predicted rather than actual values. The IV model utilized for this employed the same instruments as were used in the NL3SLS model of (4'), (6').

⁵ Unconditional standard errors were estimated by numerically calculating the system's gradient vector $\partial f(\beta)/\partial \beta$, then constructing the covariance matrix given in Amemiya (p. 963). A standard error of λB^2 was obtained in this manner, but separate standard errors for λ and B^2 could be derived only if the covariance and distributions of these separate terms were known.

Table 1. Elasticity of Corn Yield Mean and Corn Yield Standard Deviation with Respect to Selected Inputs, Linn County, Iowa, 1964–1969

Input	Conditional Beta (Nelson and Preckel) ^a	Just-Pope Method	Primal System
<u>Yield Mean</u>			
A ^c		48.85 (3.89) ^b	40.36 (4.19) [3.86]
Nitrogen (N)	0.46	0.05 (2.40)	0.02 (1.41) [6.01]
Phosphorus (P)	−0.35	−0.01 (−1.61)	0.07 (2.05) [4.36]
Potassium (K)	0.13	0.05 (0.91)	0.03 (1.90) [4.33]
Slope	−0.06	0.04 (1.14)	0.07 (1.97) [1.66]
Clay	0.99	0.18 (2.87)	0.21 (4.20) [2.73]
<u>Yield Standard Deviation</u>			
B ^c		4.87	0.21
Nitrogen (N)	0.29	0.06 (0.59)	0.09 (1.64) [3.27]
Phosphorus (P)	0.19	0.56 (1.71)	0.80 (6.67) [8.11]
Potassium (K)	−0.22	−0.22 (−0.84)	0.35 (4.12) [7.03]

^a Values for the mean were derived from Nelson and Preckel's table 3. Values for the standard deviation are one-half of Nelson and Preckel's table 5 figures.

^b Numbers in parentheses are *t*-values. In the primal system, parenthesized *t*-values are conditional on the optimal λB^2 value; bracketed *t*-values are unconditional (see text). Sample size is 103.

^c Yields are measured in bushels per acre, fertilizers in pounds per acre. Sample means were N = 83.1, P = 50.1, K = 48.8, slope = 3.3, clay = 22.1, yield = 122.7.

County model contrasts with a significantly positive effect in the system model.

All three models implied, in each county investigated, strong fertilizer impacts on yield risk. For example, raising the nitrogen application rate by 10% in Linn County increased yield standard deviation by about 1% (thus variance by 2%) in the system model and by about 3% in Nelson and Preckel's conditional beta model. Both the NP and JP models suggested some fertilizers are risk reducing (in Linn, the risk reducer is potassium). All fertilizers in the system model are, in contrast, risk increasing or nonsignificantly affect risk. Risk-portion estimates tended to differ widely among the three approaches, suggesting risk effects are more difficult to estimate accurately than are mean effects.

Substituting the primal system elasticities into (4'), taking logs of the absolute values of the resulting time series, adding 0.6352 to the expectations of the series, then exponentiating gave *B* estimates of 0.209, 1.353, and 2.031 for Linn, Muscatine, and Fayette, respectively. Combining these consistent estimates of *B* with the system estimates of λB^2 generated an absolute risk aversion (*A*) estimate of 0.016 for Linn, 0.538

for Muscatine, and 0.140 for Fayette County (1967 dollars per-acre basis). These are consistent with the common assumption that producers tend to be risk averse.

Quasi-likelihood ratio tests (Gallant and Jorgenson) were performed using the unconditional covariance estimates to determine the significance of differences between Just-Pope estimates and those obtained using the NL3SLS primal system. The null hypothesis that the mean-yield elasticities obtained from the two estimators are the same was rejected at the 0.05 level for all counties. Calculated test statistics were 869.60, 26.15, and 31.65 for Linn, Muscatine, and Fayette compared to a tabled chi-square value of 11.07 at the 5% test level with five degrees of freedom. The null hypothesis that variance-of-yield elasticities were the same between the two estimators also was rejected at the 0.05 level in every case. Statistics were 1365.23, 286.53, and 9547.71 compared to a tabled chi-square value of 7.31 at the 5% test level with three degrees of freedom. Recall, however, that differences in the two models' yield mean effects are much smaller than are differences in their yield risk effects.

Calculated values of Hausman's specification error statistic were 6.52, 2.39, and 3.05 for the three counties, compared to a critical value of 11.07 at the 5% level with five degrees of freedom. The null hypothesis of independence between input usage and the production function residual cannot be rejected at a reasonable confidence level. The Just-Pope approach thus provides reasonably consistent estimates of the production function's mean-portion parameters in the cases examined. Yet, these estimates still are less efficient than the system estimates because they fail to take account of cross-equation parameter restrictions and error correlations.

Per-Acre Supply and Input Demands

Risk aversion and inputs' effects on yield risk combine to have significant implications for per-acre supplies and input demands. Implications for Linn County are illustrated by substituting the system estimates of production function and risk aversion parameters into (6') and calculat-

ing per-acre fertilizer demands. The latter are then substituted into (8) to determine means and standard deviations of per-acre corn quantities supplied.⁶

The risk-neutral grower's potassium demand curve, which ignores potassium's positive effect on yield risk, ranged from 90 pounds per acre at 5.0¢ per pound to 140 pounds per acre at 3.5¢ per pound (1967 dollars). When risk aversion ($\lambda = 0.016$) was taken into account, marginal risk premium turned positive; demand shifted leftward and passed nearly vertically through the sample mean use rate of 48.8 pounds of potassium per acre. Linn's corn price-potassium demand relations are shown in figure 1. Here, introducing risk aversion not only steepens demand but causes it to backbend, as higher output prices exacerbate the marginal risk effect of any input increases. Possible backbending of the output price-input demand relation is one reason com-

⁶ MathCAD 2.0 was used to find numerical solutions of the optimal inputs because (6') cannot be expressed in explicit form.

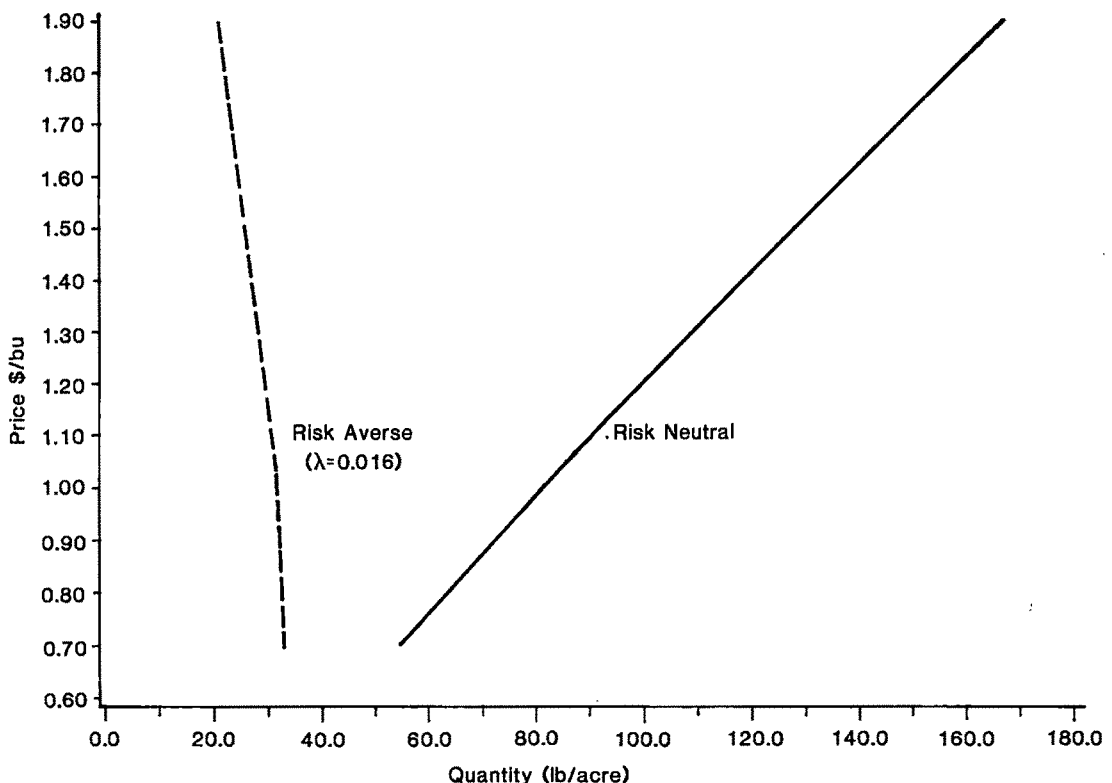

Figure 1. Per-acre potassium demand as a function of corn prices, Linn County, Iowa, 1964-69

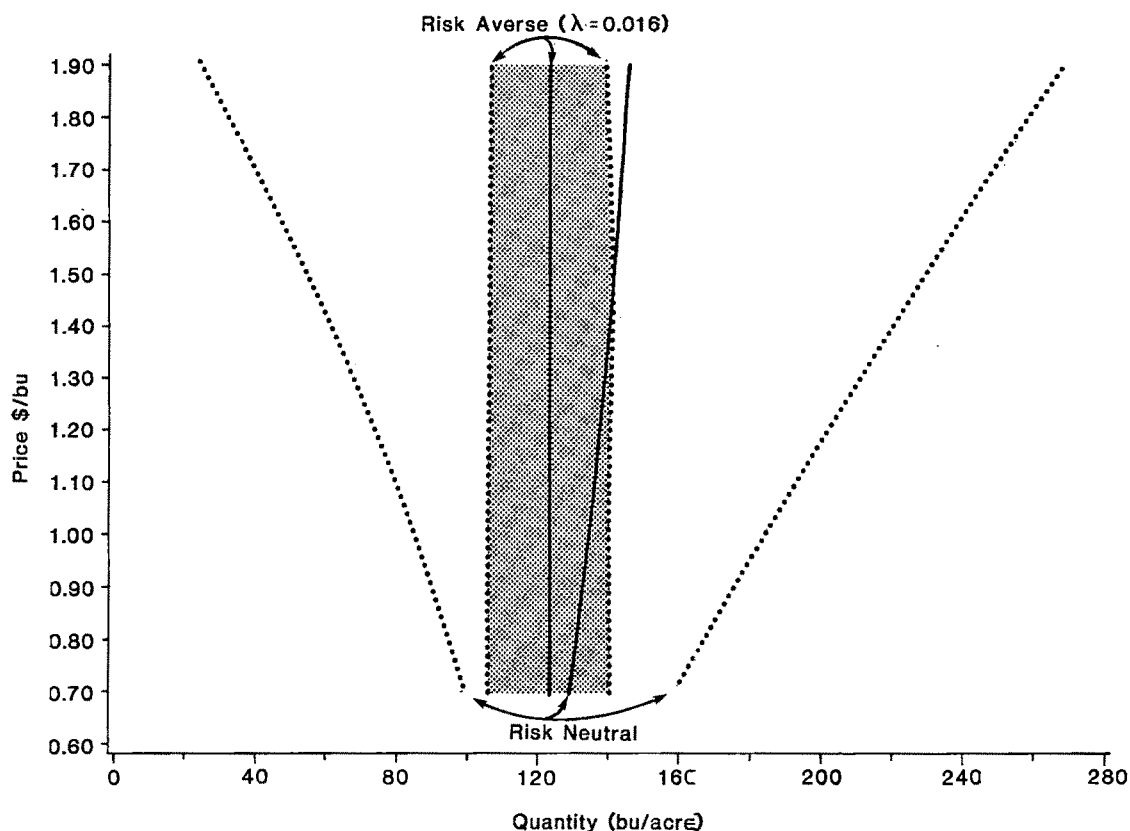

Figure 2. Mean and standard deviation of per-acre corn yield as a function of corn prices, Linn County, Iowa, 1964–69

parative statics of the risk-averse firm are so difficult to generalize (Pope and Kramer).

Finally, figure 2 gives per-acre corn supplies at various levels of expected corn price. Solid lines in the figure indicate supply expectations, while dotted lines indicate one-standard-deviation confidence intervals around these expectations. (The confidence interval for the risk-averse farmer is shaded, and the interval for the risk-neutral farmer is left unshaded.) A risk-neutral grower's relatively elastic fertilizer demands result in a slight increase in per-acre expected supply as corn price rises (right-hand solid line in fig. 2). In contrast, the risk averter's inelastic fertilizer demands combine with low mean-yield coefficients (top, table 1) to produce relatively inelastic corn supply relations (left-hand solid line in fig. 2). In fact, per-acre supply backbends slightly, reflecting the high and increasing rate at which increases in the known output price augment profit risk. Just and Zilberman also have shown that negative supply elasticities can occur under constant absolute risk aversion,

even when partial risk aversion is as low as 0.60. Average partial risk aversion for the sample of Linn County farmers was 2.34 at sample means.

The dotted confidence intervals in figure 2 indicate the extent to which yield's heteroskedasticity in inputs (bottom, table 1) leads to supply heteroskedasticity in price. Risk averters' steep input demands mean that corn price changes will little affect yield risk. For these farmers, yield variance is slightly lower at high corn prices than at low corn prices because some input uses are slightly lower at high prices as well. Risk neutrality, on the other hand, encourages greater input demand elasticity and hence a per-acre supply variability that reacts more strongly to output prices.

Conclusions

Farm technology parameters usually are assessed independently of the risk preferences of farm operators. Such separation raises practical

difficulties about sample comparability and fails to take maximum advantage of available information. We have shown that a primal system consisting of the input demands and production function may indeed be specified through which mean production, risk, and risk preference parameters can be estimated jointly. The system approach allows assessment of farmers' revealed opinions about production function relationships, including inputs' marginal impacts on yield risk. It can be used, further, to derive utility or risk preference estimates that are mutually consistent with these revealed opinions. If the model is correctly specified, consistency and efficiency generally improve compared to separate technology and utility analysis.

The approach is not without cost. Extending such a system to nonnormally distributed errors or nonconstant risk aversion is not straightforward. Incorporating nonnormal distributions into a system context probably would require using a particular nonnormal family, for example the conditional beta. Consideration of price risk also would complicate the model, and the present framework may give inaccurate risk aversion estimates in cases where price risk is substantial.

Primal system estimates of yield mean elasticities were fairly close to (but significantly differed from) those derived with a Just-Pope-type estimator. Elasticities of yield risk often differed substantially from the Just-Pope-type estimates, falling in several cases closer to the Nelson-Preckel figures. Apparently modest yield risk elasticities led to rather inelastic per-acre supplies and input demands even when risk aversion was moderate. This does not mean total supply and input demand would be inelastic as well, inasmuch as acreage may remain significantly elastic. It does, however, help explain the comparative rigidity of farm input proportions, which often is ascribed to output-maximizing behavior or asset fixity.

Construction of True Cost of Food Indexes from Estimated Engel Curves

William Noel Blisard and James R. Blaylock

This paper applies a technique to derive true cost-of-living indexes from the estimation of a simple system of piglog Engel curves. This technique allows a maximum amount of commodity disaggregation, and the indexes show the impact of inflation on households with different expenditure levels and demographic characteristics. Results indicate that the consumer price index (CPI) underestimated the cost of food over the 1980–85 period. The CPI more accurately reflects the cost of food for nonwhite households with low or average food expenditures.

Key words: Engel curves, true cost-of-living index.

Economists and government agencies have utilized various fixed-weight price indexes to ascertain how changing price levels affect consumers and to adjust the benefit levels of welfare and transfer programs. However, fixed weight indexes, such as the consumer price index (CPI), ignore the fact that consumers will substitute among goods as relative prices change, thereby altering the appropriate true weights. The result is that fixed weight indexes are biased, yet often used, estimators of the cost of living.

In order to construct index numbers based upon economic theory and to incorporate substitution effects by allowing weights to change from period to period, economists have developed "true indexes," which are typically derived from the estimated parameters of a complete demand system. However, demand systems tend to be limited to several broad categories of goods because of estimation problems; as such, they do not capture the substitution effects within the individual categories. Consequently, a true index that does not require the estimation of a demand system has been sought. One candidate, advanced by Diewert, and Fry and Pashardes, is the Tornqvist price index which, under specific conditions, is a true index. This index is easy to derive since it simply requires a knowledge of budget shares and prices over the relevant time

period. Unfortunately, this index may also fail to capture substitution effects from relative price changes because budget shares are fairly constant over time. This occurs if consumers make quantity adjustments as relative prices change but leave real expenditure levels almost constant.

The purpose of this paper is to derive true cost-of-food indexes for various demographic groups in the United States from estimated piglog Engel curves. In addition, we wish to determine if the CPI for total food over- or underestimates the cost-of-food for any demographic group. The indexes constructed in the study are based upon the premise that substitution effects can be captured by estimating Engel curves in which the intercepts may shift from one time period to another. These true indexes are closely related to the Tornqvist index but use the estimated intercepts from the Engel curves rather than observed budget shares as weights. The following sections outline the estimation of a true cost-of-living index from piglog Engel curves, discuss the entry of demographic variables into the model, and present the estimated Engel curves and several true cost-of-food indexes for various demographic profiles.

Estimating the True Cost Index of the Piglog Model

Piglog (price independent generalized logarithmic) models represent a specific class of pref-

William Noel Blisard and James R. Blaylock are agricultural economists with the Economic Research Service, U.S. Department of Agriculture.

The authors would like to thank two anonymous reviewers for their constructive comments.

ferences which permit exact aggregation over consumers (Muellbauer 1975, 1976). That is, the piglog functional forms represent market demands as if they were the outcome of a representative consumer. These preferences are represented by a cost or expenditure function which defines the minimum expenditure necessary to attain a specific utility level at given prices. This cost function is denoted as $c(u, p)$ for utility level u and price vector p . Thus, the piglog function is defined as

$$(1) \quad \ln c(u, p) = (1 - u) \ln a(p) + u \ln b(p),$$

where u lies between 0 (subsistence) and 1 (bliss). Thus, the positive linearly homogenous functions $a(p)$ and $b(p)$ are regarded as the costs of subsistence and bliss, respectively. Specific functional forms are assigned to $a(p)$ and $b(p)$ so that their first- and second-order derivatives can approximate any arbitrary cost function.

Within the context of the piglog model the true cost index for any household may be written as

$$(2) \quad \ln P(p_1, p_0; u_{hr}) \\ = [a(p_1) - a(p_0)] + [b(p_1) - b(p_0)]u_{hr}$$

for price vectors p_1 and p_0 and reference utility u_{hr} . Again, this expression can be interpreted as the cost of living at some minimum level of consumer expenditure, say, $\ln S_t = a(p_1) - a(p_0)$ and a marginal expenditure index, $\ln M_t = [b(p_1) - b(p_0)]u_{hr}$. Fry and Pashardes note that, over time, $\ln S_t$ incorporates the effects of substitution among goods, while differences in $\ln M_t$ across households reflect the distributional effects of inflation.

Utilizing the indirect utility function, the Marshallian budget shares of the piglog model can be derived from the above cost function as

$$(3) \quad w_{iht} = a_i(p_t) + [b_i(p_t)/b(p_t)][\ln x_{ht} - a(p_t)].$$

This complete demand system could be estimated, but the number of commodities or groups that could be considered is constraining. In general, a high degree of aggregation results in little substitution between the groups because most of the substitution occurs within the separate groupings. However, Fry and Pashardes propose modeling the substitution effects as shifts in the $a(p)$ part of the piglog cost function over time.

Specifically, when the piglog cost function takes the almost ideal demand system form, the Engel curve can be written as

$$(4) \quad w_{iht} = A_{it} + B_i [\ln x_{ht} - \alpha_i],$$

where $A_{it} = A_{i0} + \sum_j \lambda_{ij} \ln(p_{jt}/p_{j0})$, $t = 0 \dots T$, and α_i is the log of the observed minimum household expenditure. The A_{it} terms thus reflect the substitution effects as prices change from p_{j0} . Engel curves can then be estimated for a large number of commodities.

The estimated parameters of the above Engel curves are used to construct a base period referenced index series for any given household h :

$$(5) \quad \ln I_{ht} = \sum_i A_{i0} \ln(p_{it}/p_{i0}) + \sum_i A_{it} \ln(p_{it}/p_{i0}) \\ + [\Pi_i p_{it}^{B_i} - 1][\ln x_{ht} - \alpha_i].$$

The average of the first two indexes is the "reference household's" (minimum expenditure) true cost index. All other indexes are relative to the reference household's index; these indexes differ by the effect of their level of expenditure, which is the third term of equation (5).

The Tornqvist index is formally defined as

$$.5(w_{iht1} + w_{iht0}) \ln(p_{it}/p_{i0}),$$

where w_{iht} is the budget share for the i th good for the h th household in period $t = 0, 1$. However, instead of observed budget shares, we substitute the estimated intercept terms from the piglog Engel curves. These estimated intercepts represent the budget shares of the "reference household" and capture the substitution effects that occur as prices change from a base period. In addition, we can derive indexes for households with expenditures above that of the reference household by utilizing the marginal expenditure index.

The Tornqvist index is a true cost-of-living index if the underlying cost function is translog (Diewert) or quadratic (Fry and Pashardes). Since Engel curves related to the almost ideal demand system have an underlying quadratic cost function, the derived indexes are considered true indexes.

Incorporating Demographics into the Model

Household characteristics affect patterns of demand and cause price changes to have varying effects on the cost of living for different households. For illustration consider a household characteristic, say z , which is a continuous variable. The cost function may be written as

$$(6) \quad \ln c(u_h, p, z_h) \\ = a(p) + b(p)u_h + d(p) \ln z_h,$$

where $a(p)$ and $b(p)$ are defined above and $d(p) = \epsilon + \sum_{i=1}^r \ln p_{it}$.

Intercept shifts for each time period capture the substitution effects, and the Engel curves are estimated as

$$(7) \quad w_{iht} = A_{it} + B_{it}(\ln x_{it} - \alpha_t - \eta \ln z_h) + \zeta_i \ln z_h,$$

where η is the equivalent income scale at base period prices (Fry and Pashardes). Our strategy was to group the data by the z demographic variable, so that the $\eta \ln z_h$ term could be absorbed into the definition of the minimum household expenditure, α_t , for the appropriate demographic group.

Traditional zero-one dummy variables can account for various noncontinuous demographic effects such as race and region for both the intercept and the slope parameters. Demographic effects for race, region, and household size are captured in this study.

Empirical Results

True cost-of-food indexes were constructed from Engel curves estimated from data taken from the "Continuing Consumer Expenditure Survey" (CCES) for the years 1980 through 1985. The CCES contains two components, each with its own questionnaire and sample. The first is an interview panel survey in which approximately 5,000 households are surveyed every three months over a one-year period. The second is a diary survey of approximately the same sample size in which households keep an expenditure diary survey for two consecutive weeks. This latter survey obtains data on small, frequently purchased items that are normally difficult to recall, including food and beverages.

By using this survey we considered sixteen food categories: beef, cereal and bakery products, dairy products, eggs, food-away-from-home, fresh fruit, fish, fats and oils, fresh vegetables, nonalcoholic beverages, other meats, pork, processed fruit, processed vegetables, poultry, and sugar and sweeteners. The individual CPI's which correspond to the above sixteen food groups and which comprise the CPI for total food were used as proxies for price. The estimated equation for each of the sixteen food groups is

$$(8) \quad W_{iht} = A_{it} + A_{inc}D_{nc} + A_{is}D_s + A_{iw}D_w + A_{ir}D_r + Z_{iz} \ln z_h + (Y_{it} + Y_{inc}D_{nc} + Y_{is}D_s + Y_{iw}D_w + Y_{ir}D_r)(\ln x_{it} - \alpha_t),$$

where $t = 1980 \dots 1985$ and the A and Y sub-

scripted variables are dummy shifters for the intercept, A_{it} , and slope, Y_{it} , for the North Central, South, West, and race. In addition, we have the intercept shift parameter for household size, Z_{iz} . For this variable z_h is the log of the family size equivalent scales implicit in the official poverty thresholds published by the Bureau of the Census. $\ln X_{ht}$ is logged household expenditure on total food. Finally, α_t is the log of the observed minimum household expenditure on total food for each demographic group, e.g., nonwhite households in the Northeast or nonwhite households in the South.

The estimates for the sixteen Engel curves are presented in table 1. For each equation, A_{80} through A_{85} represents the intercept for the Northeast for each year of data. A_{nc} through A_w represent regional dummy variables for the North Central, South, and West. Z is the estimated coefficient for household size, and A_r is the demographic dummy variable for race.

Slope expenditure parameters are represented by Y through Y_r , where Y represents the estimated expenditure coefficient for nonwhites in the northeast, and Y_{nc} , Y_s , and Y_w , are the estimated dummy slope shifters for expenditures by nonwhites in the North Central, South, and West, respectively. Y_r is the dummy expenditure slope shifter for whites. R^2 is the goodness of fit of each equation, and F is a significance test between estimating an intercept for each year versus one common intercept for all years. Many of the estimated coefficients are highly significant.

Variation in the intercepts is a necessary condition the presence of substitution effects and the F -tests indicate that most equations are better represented by allowing the intercept to shift from one period to another versus a single estimated parameter. Exceptions include fresh fruit, fish, processed vegetables, and sugar and sweeteners. Apparently, little substitution occurs between these four categories and the others. For instance, households may substitute one kind of fruit for another but may not substitute fresh vegetables for fresh fruit. In addition, the Pearson correlation coefficient between changes in the intercept terms and changes in the individual CPIs was .73, which supports the argument that shifts in the intercept terms capture the substitution effects. A rigorous proof of this would be to calculate the implied substitution coefficients and then check for concavity. However, we have more parameters than equations and cannot provide this check. We will return to the subject of substitution below.

Comparing the estimated intercepts for any

given year with the preceding year indicates the food group substitution pattern for the representative household. In comparing 1981 with 1980 we see that the budget shares for beef, food-away-from-home, fish, fats and oils, nonalcoholic beverages, and poultry decreased, while the remaining categories increased. Hence, the representative households substituted away from these categories into the others.

As noted above, true cost indexes for reference households can be calculated from the estimated intercepts of the Engel curves. Marginal "demographic" indexes, calculated from the coefficients that shift the intercepts, can be utilized to construct indexes which take into account the effects of race, region, and household size. In turn, marginal "expenditure" indexes, calculated from coefficients which shift the slopes of the Engel curves, can be utilized to construct indexes which take into account expenditures

above those of the reference household by race and region.

A true cost-of-food index was constructed for a reference household defined as a nonwhite single-person household in the Northeast; it is presented in table 2. In addition, we have indicated how the reference household can be adjusted to account for demographic effects by race, region, and household size, as well as marginal expenditure effects by race and region. Over the 1980-85 period the true cost of food for the reference household rose 21.8%. White reference households experienced a greater inflation rate than the nonwhite reference household. These values ranged from .1% higher in 1981 to .7% in 1983. Similarly, the three regional marginal indexes are all greater than 100.0, which indicates that the reference household in the Northeast experienced the lowest rate of price increase. While both the North Central and South

had similar rates of price increases, the West experienced the highest rates of increase.

The demographic marginal indexes for household size are included in table 2. Each value for household size 2 through 5 is below 100.0 after 1980, generally decreasing in magnitude over the six years. This pattern indicates that, relative to a single-person household, the true cost-of-food falls as household size increases. Intuitively, this may seem contradictory. However, the sixteen food categories include food-away-from-home, which experienced one of the largest price increases of all food categories. The data indicate that per capita food spending declines for this category as household size increases. In 1981 a two-person household experienced an inflation rate that was .1% lower than a single-person household, while a five-person household experienced a rate that was .4% lower than a single-person household. In 1985 the cumulative rates experienced by a two- and five-person household were .5% and 1.8% lower, respectively, than a single-person household.

Finally, marginal expenditure indexes are also shown in table 2. These marginal indexes are used to construct true cost-of-food indexes for households with expenditures greater than the reference household. They indicate the response of the reference index to a 1% increase in total food expenditure. The race variable for white households is again greater than 100.0, indicating that the true cost-of-food index increases as expenditures increase above that of the reference household relative to nonwhites. However, the three regional expenditure indexes are all less than 100.0, which indicates that consumers in the Northeast have a larger marginal expenditure index than consumers in the other three regions. These regions have similar marginal expenditure indexes and are just slightly less than that of the Northeast. Hence, while the Northeast should have the lowest value index for the reference household, those Northeast households with expenditures greater than the reference household may have true indexes greater than those of the North Central, South, and West.

Table 2. Reference Household Index and Effects of Demographic Adjustments

Year	Reference Index	Marginal Demographic Region				Household Size				Marginal Expenditure Region			
		Northeast Race	North		West	2	3	4	5	Race	North		West
			Central	South							Central	South	
1980	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0	100.0
1981	107.9	100.1	100.1	100.1	100.2	99.9	99.8	99.7	99.6	100.0	99.9	99.9	99.9
1982	112.0	100.5	100.3	100.3	100.4	99.8	99.7	99.5	99.4	100.1	99.9	99.8	99.9
1983	114.2	100.7	100.4	100.5	100.6	99.7	99.5	99.1	98.9	100.3	99.9	99.8	99.9
1984	119.0	100.5	100.5	100.4	100.7	99.7	99.3	99.0	98.7	100.3	99.9	99.8	99.8
1985	121.8	100.2	100.4	100.7	100.9	99.5	99.1	98.6	98.2	100.4	99.9	99.7	99.8

Table 3 elaborates upon the effects of substitution obtained from using the intercept parameters to construct relevant indexes. The first column repeats the reference index from table 2. The second column is the fixed base expenditure weighted index. This index lies below the Tornqvist index because these effects refer to substitution between expenditures rather than quantities of goods. The current weighted index lies above the Tornqvist as expected. These results suggest that an index which uses expenditure shares as weights can be a good approximation to the true index in the case of total food. Conversely, this implies that a quantity share index would be a poor approximation to the true index.

A quantity-share-weighted index is calculated using the fact that $A_{it} = p_{it}q_{it}/x_t$, where q_{it} is the quantity purchased by the reference household. Since the Tornqvist index is the true cost-of-food index corresponding to x_t , $A_{it}S_{it}/p_{it} = \omega_{it}$ is the quantity share of the i th good. Thus, $\sum \omega_{i0} \ln(p_{it}/p_{i0})$ and $\sum x_{it} \ln(p_{it}/p_{i0})$ are the fixed based and current weighted indexes which use the quantity shares as weights. These indexes are reported in the last two columns of table 3.

As expected, the index which uses the base period quantity shares overstates the cost of food, while the index which uses the current period quantity shares understates the true cost of food. Importantly, the biases of these two indexes are larger than those of the expenditure indexes. Thus, the shifts of the intercept terms of the Engel curves appear to capture the substitution effects resulting from relative price changes.

With this background, other cost-of-food indexes constructed from the estimated Engel curves can be considered. Table 4 indicates constructed indexes for a reference (least expenditure) single-person household as well as for single households with average and high expenditures.¹ Indexes were constructed for the total sample (all singles), nonwhites and whites, as well as by region. Average expenditure (the average weekly household expenditure in the sample) ranged from \$56.87 in 1981 to \$67.60 in 1985. The high expenditure level was one standard deviation above the mean values. The standard deviation was approximately \$40.00 for each year in the sample.

¹ Conditional expenditure elasticities can be calculated from a knowledge of budget shares and the expenditure coefficients using the formula $\epsilon_i = 1 + B_i/w_i$. Contact the authors for the appropriate budget shares.

Table 3. True Index for Reference Household and Substitution Effects

Year	Reference Index	Expenditure Share Base	Weighted Current	Quantity Share Base	Weighted Current
1980	100.0	100.0	100.0	100.0	100.0
1981	107.9	107.2	108.6	108.7	107.1
1982	112.0	111.0	113.0	113.1	110.9
1983	114.2	112.7	115.7	115.8	113.5
1984	119.0	117.7	120.3	121.0	117.3
1985	121.8	119.0	124.6	124.8	118.5

Table 4 and the least expenditure indexes indicate that each individual index is above the CPI. This relationship also holds for those households with expenditures above the reference household. Other things equal, the true index should lie below the CPI since it allows for substitution among the sixteen food categories. However, over the 1980–85 period households increased their budget share of food away from home. This category also had a large price increase over the sample period. However, because the CPI is a fixed weight index, it underestimates the increase in total food prices. Note also that the indexes in table 4 are for single-person households, and that the data indicate that these households allocate a larger budget share to food away from home than do larger households.

In the individual categories, whites have a higher index than nonwhites and the Northeast and West have the lowest and highest indexes of the four regions, respectively. This result was expected from the discussion of the demographic marginal indexes. For the reference households the differences in the indexes for the races are slight, amounting to .1 of a point in 1981 and .2 of a point in 1985. Similarly, differences among regions are small, ranging from .2 of a point difference between the Northeast and the West in 1981 to .9 of a point between the same two regions in 1985.

When expenditures above that of the reference household are considered, whites have a higher average expenditure index than nonwhites, but now the South has the lowest index, while the West again has the highest. This pattern occurs because the South has the lowest marginal expenditure index of the four regions. In general, the difference in the indexes between the races is greater than between regions. This result is not totally unexpected because differences in income received are probably greater

between the races than between the regions. Hence, even given the same dollar amount of food expenditures, buying patterns between the races is different, as was shown by the race variable in the estimated Engel curves. While part of this effect is surely due to asset or wealth disparity, some may result from cultural differences.

Considering the high expenditure level in table 4, the same pattern holds that appeared with the average expenditure category, except the differences between the races again widen. Thus, whites have a true cost-of-food index which is .4 of a point higher than nonwhites in 1981, and 1.3 points higher than nonwhites in 1985. Undoubtedly, the difference is because whites allocate a larger share of their food expenditures to the food-away-from-home category.

Table 5 indicates the true cost-of-food index for an average size family with average food expenditures with the same demographic characteristics as table 4. As shown in the table, average family size over the period in question was 2.5 people. Relative to the CPI, the true cost-of-food index for the total sample is still greater but by a smaller margin as a result of the negative effect of household size. Hence, the true cost index is .3 of a point higher than the CPI in 1981 and 1.4 points higher in 1985. However, the index for nonwhites is much closer to the CPI. The indexes are the same in 1981 and differ by .5 of a point in 1985. Across regions all the true indexes are above the CPI; again, the West has the largest true cost-of-food index as before.

When household size is increased to four people in table 5, the same pattern is found except the calculated index for nonwhites is below that of the CPI. However, the index for the total sample is very close to the CPI, .2 for a point higher in 1981 and .5 for a point higher in 1985. The largest difference occurs in 1984 when the

true index is .9 of a point higher than the CPI. The regional patterns are the same as before.

Conclusions

We have applied a technique in which true cost-of-food indexes are derived from the estimation of a simple system of Engel curves. This method demonstrates the feasibility of deriving cost-of-food indexes without estimating a complete demand system. Consequently, a large number of commodity groups can be considered and the substitution effect between the groups captured. Also, indexes for various demographic groups in society can be constructed from survey data.

In general, the results indicate that the CPI underestimated the cost of food over the 1980–85 period. The CPI more accurately reflects the cost of food for nonwhite households with low or average food expenditures and with four or more household members. Conversely, the CPI underestimates food costs the most for small white households with average or above food expenditures. However, most of the true cost-of-food indexes which we calculated were close to the CPI for total food. In this sense, the CPI was a fairly good indicator of total food costs for the above groups over the study period.

Wife's Employment, Food Expenditures, and Apparent Nutrient Intake: Evidence from Canada

Susan Horton and Cathy Campbell

Women's employment has important effects on the share of food in total expenditure, the share of food-away-from-home in the food budget, cost per calorie, and per capita availability of twelve nutrients. Empirical results are presented using Canadian household food expenditure survey data. As expected, wife's employment increases the share of food-away-from-home in the food budget. Wife's full-time employment has a negative effect on apparent nutrient intake, not offset by the higher per capita income of such households. There are policy implications for nutrition education and nutrient content of food-away-from-home.

Key words: apparent nutrient intake, Canada, food-away-from-home, food expenditures, household survey, wife's employment, women's employment.

The increase in women working outside the home has had important economic effects. One effect involves food expenditures, both in terms of patterns of eating out and the types of foods prepared in the home, with consequent effects on nutrient availability. This study examines the effect of wife's employment on an extensive set of variables describing food behavior. The variables include the share of food in total expenditure, the share of food-away-from-home (FAFH) in the food budget, price paid per calorie, and the per capita availability of twelve nutrients. The results are of potential interest for food policy, for nutrition education, and for programs which aim to affect the nutrient composition of food eaten outside the home (restau-

rant food, fast food, school meals, etc.). In addition, this is the first time that public use data tapes of Canadian national food expenditure surveys have been available for use in research. The remaining sections of this paper review the literature, discuss the methods, data, results, and conclusions of the study.

Literature Review

Several empirical studies have examined the effects of wife's employment status, mostly for the United States. Expenditures on food-away-from-home generally increase where the wife works outside the home (e.g., McCracken and Brandt, Kinsey, Sexauer, and two studies cited in Morgan, by Morgan and Goungetas and by Haines). Capps, Tedford, and Havlicek also found that households where the wife is not employed outside the home spent a larger share of the food budget on nonconvenience foods and a smaller share on "complex convenience foods." Barewal showed that households in Canada headed either by a single adult or by a couple where both worked full time outside the home spent 50% more on restaurant food than households headed by a couple where the wife worked full time in the home. However, because this study used only univariate analysis, the wife's

Susan Horton is an associate professor, Department of Economics, University of Toronto; Cathy Campbell is an assistant professor, Division of Nutritional Sciences, Cornell University.

This analysis is based on the 1984 Survey of Family Expenditures, Statistics Canada. All computations on these data were done by the authors, and responsibility for their use and interpretation is entirely that of the authors.

The authors would like to thank the Family Expenditures Section of Statistics Canada and in particular Ulysse Neveu for assistance in obtaining the household data. Thanks to Agriculture Canada and in particular Linda Robbins for assistance in obtaining the nutrient composition data for specific foods. The authors are grateful to Duncan Thomas and three anonymous referees for helpful comments on an earlier draft. Paul McGuire gave invaluable assistance with some of the computations, and Monica Neitzert and Douglas Tisdall provided capable research assistance.

work status effects could not be distinguished from other household composition and income effects. Fewer studies have considered the effects of wife's employment status on nutrition, and the findings of these studies are less conclusive. Adrian and Daniel (using expenditure data) found no significant difference in nutrient intake between households where the wife was employed and those in which the wife was not employed.

For developing countries the effects of wife's employment status has been widely studied, often within the context of new household economics models. The effect on food expenditures has received little attention because restaurant expenditures are far less important than in high income countries. However, one study by Senauer, Sahn, and Alderman documented that a higher wage (actual or imputed) of the wife was associated with a shift in consumption away from rice (which involves more preparation time) and toward bread (which is more convenient) in Sri Lanka. Several studies have used anthropometric measures to examine the effect of wife's employment on nutritional status. Tucker and Sanjur surveyed a number of studies for the Philippines, Ghana, and Kerala and found mixed effects. In Tucker and Sanjur's study of Panama, wife's employment status was positively associated with intake of protein, calories and calcium, and with hemoglobin level and anthropometric measures.

Methods

Women's employment outside the home has several possible effects on consumption patterns. First, higher household income from the wife's employment would increase consumption of all normal goods and increase the budget share of luxury goods. Second, the new household economics framework suggests that wife's employment would cause a shift from consumption of time-intensive toward goods-intensive commodities. Other effects result from changes in control over household income. Income earned by the wife may give women a greater say in household expenditure decisions, especially for expenditures on children and on basic needs including food (e.g., Dwyer).

The present study uses three measures of food expenditures: the share of income spent on food, the share of the food budget allocated to food-away-from-home, and cost per calorie of home-prepared food (food purchased in food stores).

The last variable reflects the widely observed phenomenon that as incomes rise, households allot more of the food budget to changing the type, quality, and variety of foods rather than increasing the quantity of calories consumed. The study also examines daily per capita availability of twelve nutrients (calories, protein, fat, carbohydrate, folate, calcium, iron, vitamin A, vitamin C, thiamine, riboflavin, and niacin).

The following budget equations are estimated:

$$\begin{aligned} \text{food share of income} &= f(Y, P, Z), \text{ and} \\ \text{FAFH share of food expenditure} &= g(Y, P, Z), \end{aligned}$$

where Y is per capita income, P is a vector of prices, and Z is a vector of demographic characteristics including wife's employment status.¹ Nutrient availability per capita and cost per calorie (an indicator of tastes for noncaloric aspects of food) are treated as derived demands, and similar equations are estimated:²

$$\begin{aligned} \text{cost per calorie} &= h(Y, P, Z), \text{ and} \\ \text{nutrient availability} &= n(Y, P, Z). \end{aligned}$$

A quadratic specification of income per capita was used (other specifications such as log-linear and log-quadratic were also tried, with similar results). Since cross-section data are used, region and seasonal dummies capture price effects. Household composition is represented by the number of adults sixteen to sixty-five years, the number of adults over sixty-five, and the number of children. These variables control both for scale effects as well as differences in nutrient requirements by age. Entering household composition variables directly is more flexible than using adult equivalency scales. Unfortunately, the data do not indicate the sex composition of the household (other than information on headship). Dummy variables for education of the head of household were included (some post-secondary other than a university degree/university degree/with the omitted dummy being secondary education or less). The male household head's education is the one which is used in households headed by couples. Dummy variables are also used to capture wife's working status (households with a male head, no wife/

¹ Per capita income equals total household income divided by number of household members.

² Per capita nutrient availability equals total nutrients available per household divided by number of household members. To allow for the fact that individual requirements vary by age, age composition variables were entered separately (the data tape did not contain details on sex composition of the households).

households with a female head, no husband/ households headed by a couple where the wife works full time in the market/ households headed by a couple where the wife works part time in the market/ with the omitted dummy being households headed by a couple where the wife works full time in the home).³ A house ownership dummy was included (the omitted dummy being renters and tenants) because house ownership frequently affects the facilities available for home food preparation and lifestyle differences.

Because the wife's employment variable is considered endogenous, instrumental variables were used for the two dummy variables reflecting wife's work status (full-time and part-time market work).⁴ These instruments were the following: wife's country of birth (North America, the UK, other European countries, and the rest of the world), wife's first language (English, French, or other), and wife's age (6 variables representing 10-year age groups).⁵

The estimation method was ordinary least squares (OLS), with instrumental variables for the wife's work status. For the FAFH share variable, 20.3% of the sample did not eat out in the reference period. Zero observations cause potential estimation problems. If these are true corner solutions, tobit is the preferred approach for single equation estimates. Wales and Woodland, and Lee and Pitt make suggestions as to an appropriate estimation technique where a set of budget equations is estimated. However, if the zeroes result from infrequent purchase and/ or measurement error, then OLS is the most appropriate method (Deaton, Ruiz-Castillo and Thomas). It is likely that almost all households purchase some food-away-from-home at some point during the year; therefore, OLS is the appropriate technique. Because some previous studies (e.g., McCracken and Brandt, Kinsey) have chosen to use tobit when analyzing food-away-from-home, tobit estimates for this equation are presented in an appendix table, purely for comparative purposes. OLS was also used

in the equations using instruments to predict values for the wife's work choice variables.

Given this model, the likely effect of wife's work status on the food variables of interest now can be predicted. The equations control for the effect via household income. Therefore, one observed effect is caused by differences in the value of time (wife's employment would cause a substitution away from consumption of time-intensive commodities and toward goods-intensive commodities). The other effect results from wife's bargaining power in expenditure decisions. The effect on the share of food in total expenditures is ambiguous because it is not clear whether food is a time- or goods-intensive commodity, and whether wives with greater bargaining power would necessarily buy more food. Wife's market work likely would increase the share of food-away-from-home in the food budget, as well as the cost per calorie of home produced food. The effect on nutrient intake is not clear a priori.

Data

The data are from the 1984 Family Food Expenditure Survey of Canada. These data have been collected almost every two years since 1953 (Statistics Canada). Previous published studies of the Canadian Family Food Expenditure Survey have been restricted to cross-tabulations of the data (Barewal, Hunt, Karamchandani and Robbins, Mathieson and Robichon-Hunt, Nevraumont, Robbins).

In the 1984 survey, information was collected on socioeconomic characteristics of the household, and a diary on type of food, quantity, and expenditure by type of store for detailed food categories was maintained for two consecutive weeks. Food expenditures in restaurants were recorded separately, by type of restaurant and type of meal (breakfast, lunch, dinner, snack). Of the original data tape covering 5,542 households in fifteen cities, 5,188 records were usable for the expenditure analysis, and 4,746 for the nutrient availability analysis. The small sample loss included households who only participated in the first week of the survey (less than 1% of households), households who did not state their income (about 4% of the sample), and households who reported either zero income or zero food expenditure (less than 1% of the sample). Variable means for the excluded households were examined separately and did not differ significantly from the rest of the sample in

³ Statistics Canada defines full-time work as an individual working more than 48 weeks in the last 12 months, of which 25 weeks must be full-time employment. Part-time work is between 1 and 48 weeks, or more than 48 weeks but with less than 25 of these weeks full time.

⁴ The part of income which depends on wife's earnings is also endogenous. However, income was not given by source in the data set, and no suitable instruments for income were available.

⁵ Wife's work status = $f(\text{country of birth, first language, age})$. The instruments include variables likely to affect women's labor force participation but not highly correlated with food expenditures.

those socioeconomic characteristics of interest in this study.

The nutrient analysis was restricted to "housekeeping households," defined as households which ate at least one meal at home each week of the survey and which ate over half their meals from home supplies during the two-week period. For households eating the majority of their meals outside the home, food consumed at home provides an unreliable guide to nutrient availability. This condition excluded a further 8% of the households.

Because no recent national nutrient intake survey data for Canada are available, apparent nutrient intake was also constructed from the expenditure data.⁶ The conversion from food quantities to nutrients was based on Canadian Nutrient File conversion factors obtained from Agriculture Canada. The adjustment from nutrient availability from home sources, to total nutrient availability, was undertaken as follows. The number of meals consumed from home supplies was calculated (equal to the number of members at home times 21 meals per week, less

the number of meals consumed by guests in the household, less the number of meals consumed by household members elsewhere as guests or on expenses, less the number of meals consumed in restaurants). The ratio (M) of total meals consumed per week by household members to total meals consumed per week from home supplies was then calculated. Total nutrient availability for the household was obtained by multiplying nutrient availability from home supplies by the ratio M . Thus, we are assuming implicitly (following Adrian and Daniel, Mathieson and Robichon-Hunt, etc.) that a meal eaten away from home has the same nutrient value as the one missed at home.

However, unlike Adrian and Daniel, and Mathieson and Robichon-Hunt, we allowed for different sized meals at different times of day. The distribution of nutrients over the day was dinner 50% lunch 27%, and breakfast 23% (Kennedy et al.).⁷ Meals eaten by non-family members, and meals eaten out by household members as guests and on business expense accounts were evaluated as 33.3% of the day's nutrients. Food purchased and eaten outside the home as snacks

⁶ More accurate techniques for obtaining information on nutrient intake might be utilized; however, expenditure data provide some useful information on patterns of intake, given a large enough sample. For example, Nelson, Dyson and Paul compared nutrient data from household expenditure data and from a partially weighed method. They found no consistent bias from using one or other technique.

⁷ For example, in a household consisting of a single adult, if 2 dinners and 1 lunch were consumed in restaurants in one week, then $(7 - 2 \times 0.5 - 1 \times 0.27) = 5.75$ "day-equivalents" were consumed from home stores. Weekly intake was then $7/5.73$ times the intake from home sources.

Table 1. Means of Food Variables, by Wife Working Categories

Variable	Type of Household, by Wife's Work Status				Female Headed
	No Wife	Wife Works Full Time in Market	Wife Works Part Time in Market	Wife Works Full Time at Home	
Per capita income (\$'000/year)	16.987	16.419	11.064	9.626	11.900
Food share	0.180	0.124	0.168	0.186	0.205

Sample size	513	1,010	839	1,271	1,113

Notes: Means given to at least 3 significant figures. Canadian dollars are used throughout the study. See variable definitions in table 2.

(1.5% of total food expenditure) was not considered.

Three deficiencies in the data should be cited. For certain variables (particularly age and income) extreme values were not coded exactly, but as a range (e.g., age over 75 was coded as "76 and over"), in order to protect confidentiality.⁸ Second, the absence of information on sex composition of the household was a problem for the nutrient analysis. Third, Statistics Canada food item categories do not correspond exactly to Agriculture Canada Canadian Nu-

trient File categories. For example, Statistics Canada combines expenditures on lemons and limes, whereas Agriculture Canada has separate nutrient conversion factors for these two items.⁹

Results

Table 1 contains results from univariate analysis of the data. Mean values for some food and nutrient variables are provided for five groups of

⁸ A point estimate was used for these variables.

⁹ Agriculture Canada provided data on the average proportion of expenditure allotted to individual items within these mixed categories to permit conversion to nutrients.

Note: Figures in brackets are daily recommended nutrient intakes for males aged 36-50 years (source: Health and Welfare Canada 1983).

households: households headed by a male adult, households headed by a female adult (in both cases with no spouse present), and three households headed by couples, where the wife works full time in the market, part time in the market, or full time in the home.

Per capita income and household size both affect food expenditure patterns. Consistent with theory, households with higher per capita income spend a lower share of their income on food, a higher share of food expenditures in restaurants, and more per calorie on home-pre-

pared food. Households headed by a single adult similarly allot a higher share of income to food and have a somewhat higher propensity to eat in restaurants and to buy more expensive home-prepared foods. In a univariate analysis, separating the effect of wife's employment status from the effects of income and household composition is difficult.

The nutrient availability results are of some potential concern. In eleven of the twelve cases, the households with the lowest apparent per capita intake are those where the wife works outside

Notes: Figures in brackets below coefficients are *t*-statistics. Triple asterisk indicates significant at 1% level, one tail test; double asterisk indicates significant at 5% level, one tail test; single asterisk indicates significant at 10% level, one tail test. Coefficients are given to 3 significant figures, and *t*-statistics to 2 decimal places.

the home. This is somewhat surprising because these households have higher per capita incomes than households where the wife works full time in the home. Although households where the wife does not work in the market have the lowest per capita income of the five household types, in only one of the twelve cases does this household type have the lowest apparent per capita intake of a specific nutrient.

Tables 2, 3, and 4 contain the results of the multivariate analysis. Table 2 presents variable definitions, means, and standard deviations for the regressions, while tables 3 and 4 present the regression results: table 3 for the expenditure variables (share of food in income, share of

FAFH in food expenditures, and price per calorie of home-prepared food), and table 4 for the twelve nutrients.

The results for food expenditure, presented in table 3, generally confirm the findings from previous studies for other countries. Higher per capita income is associated with a decreased food share (Engels' law), but a shift occurs to more costly types of food as evidenced by an increase in FAFH share and a rise in the cost per calorie of home-produced food. The effect diminishes as income increases, as shown by the opposite sign of the squared terms. All the coefficients on income and income squared are significant. Household size has strong effects on food con-

sumption: larger households allot a smaller share of income to food, a smaller share of the food budget to eating in restaurants, and buy cheaper food at home. There are three coefficients on household size variables in each of three equations: all nine are negative, seven of them significantly so.

House ownership is associated with a significantly lower restaurant share and a significantly lower cost per calorie of home-produced food. These results may reflect different preferences for home-based activities by owners and renters; nonowners may also face less adequate cooking facilities. More education of the household head is associated with a larger share of food in total

expenditures, a larger share of restaurant food in food expenditures, and a higher cost per calorie of home-prepared food. Two education dummy variables are in each of three equations, and all six of the coefficient are positive and significant. Education clearly has a large effect on tastes. Campbell and Horton, and Horton and Campbell examine these effects in more detail.

The variables of most interest in this study are those representing wife's employment. The reference group is households where the wife works full time in the home (once the norm for households, now representing just under a quarter of all households in the survey). Compared to this household type, all other households spend more

per calorie for home-prepared food, even controlling for per capita income; the effect is significant in two of the four cases. Other households also spend a significantly greater share of the food budget on FAFH. This result supports cost-of-time interpretations, i.e., households where the wife works full time in the home substitute the wife's time for purchased inputs in food preparation. Male-headed households with no wife present are likely to spend more on food as a proportion of their income. Despite changing sex roles in housework, food preparation still remains a primarily female responsibility. Men without wives are substantially less likely to cook for themselves and likely prepare more convenient, and usually more costly, items when they do cook. Men also have higher requirements for most nutrients than do women.¹⁰

Table 4 presents the results for apparent per capita intake of twelve nutrients. Although the number of significant coefficients is large, the explanatory power of the equations is not high. This is to be expected; food expenditure data (unlike nutrient intake data) are subject to changes in food stocks. Purchase of a large bag of flour or container of cooking oil in one week is likely to inflate substantially apparent nutrient intake. This stocking behavior cancels out over a large enough sample; however, it makes prediction of nutrient availability by an individual household a hazardous procedure.

Per capita income is associated with significantly increased apparent intake of all twelve nutrients but at a rate decreasing with income (the squared term is always negative, significantly so in 8 cases). Household size variables have a negative impact on nutrient availability in all thirty-six cases, significant and negative in thirty cases. The different sizes of the coefficients reflect different nutrient requirements by age. House owners, despite allotting a lower share of the budget to food and buying less expensive foods, have higher apparent per capita intake of all nutrients (10 out of 12 coefficients are significant). The education variables have interesting effects, suggestive of increased concern for health at higher levels of education. There is a positive effect on most nutrients, significant for vitamin C and calcium for both post-secondary and university education and significant for university education for vitamin A and folate.

However, university education has a negative effect on calories, fat, niacin and thiamine, and post-secondary education has a negative effect on thiamine (intake of the B vitamins is frequently correlated with calorie intake).

Finally, the results for the wife employment status variables are compared to the reference household (households headed by a couple, where the wife works full time in the home). Households headed by a female with no husband consume less of ten of the twelve nutrients, significantly less in six cases; women have lower requirements than men for most nutrients. Conversely, households headed by a male with no wife consume more of eleven of the twelve nutrients, significantly more in four cases. Households where the wife works full time in the market consume less of all twelve nutrients (significant in 8 cases) and households where the wife works part time consume less of four nutrients and more of eight (however, none of the effects are significant). Even holding constant household size, age composition, and income, there are very strong effects of wife's full time employment status on nutrient availability.

Because this conclusion is potentially contentious, some additional work was done on dietary adequacy (Campbell and Horton); those results are summarized here. Dietary adequacy norms for Canada exist for ten of the twelve nutrients (the exceptions are fat and carbohydrates). These recommended nutrient intakes (RNI's: Health and Welfare Canada 1983) are similar to the U.S. RDA's. Nutrient requirements were calculated for each household separately, using the household age composition information. As discussed earlier, the family food expenditure survey data has only fairly broad age categories and no sex composition data. Therefore, nutrient requirements were constructed for these broad age categories using the 1986 census population weights. Households were then categorized as having adequate or inadequate diets for each of the ten nutrients.

The results of this analysis found that a non-trivial fraction of diets were classified as inadequate, ranging from a low of 6.2% (vitamin A) to a high of 52.4% (folate). Multivariate analysis was undertaken to estimate the probability that the household had an inadequate diet for a particular nutrient.¹¹ The same independent variables were used as before, and probit meth-

¹⁰ The tobit results for the FAFH share are fairly similar to the OLS ones, although some of the coefficients on the region and quarter dummies change sign. Note that the standard errors in the appendix table are not exactly correct; they have not been corrected for the fact that instrumental variables were used in conjunction with the tobit estimates.

¹¹ It has been suggested that adequacy measures for single nutrients are less meaningful than adequacy measures for groups of nutrients. Pete-kin, Kerr and Hama suggest an adequate diet should contain 80% of the RDA's for 11 nutrients, and Huffman suggests it should contain 100% of the RDA's for 13 nutrients.

ods were used to estimate the probability that a household had an adequate diet. A negative effect of wife's full-time employment was found for all ten nutrients, significant in eight cases. Thus, the adverse effects of wife's employment status cannot be dismissed by arguing that the effect exists only for households who are already exceeding their nutrient requirements.

It is possible that the RNI's are set rather high and that households with working wives are restricting their intake for health reasons. Although limiting intake of calories, fats, and carbohydrates might seem desirable, this is less clear for calcium or iron. These households might compensate by consuming more vitamin and mineral supplements, and it would be desirable to explore this possibility in future food expenditure surveys.

Finally, although the effect of the wife's higher cost of time might reduce nutrient intake, this is offset by the higher per capita income of households with wives employed in the market. As shown in table 1, however, the effect of higher income is not large enough to offset the other adverse effects, and households with wives working outside the home end up with lower nutrient availability.

Conclusions

This study has analyzed the behavior of a set of summary variables describing food expenditures and nutrient availability (3 expenditure variables and 12 nutrient variables) for a large national sample of urban households in Canada. As in previous studies, income, household size, and house ownership have important effects, and higher levels of education are correlated with increased attention to health consideration in food selection. Wife's employment status, via its effects on cost of time, leads to a higher share of restaurant food consumption and a higher cost per calorie of home-prepared food (similar to findings of McCracken and Brandt, and Kinsey, for the U.S.).

There are negative effects on nutrient availability for households where the wife works full time in the market. The higher per capita income available to these households does not offset the cost-of-time effect, and there is no evidence that higher wife's income leads to increased expenditures on "basic needs." Out of the five household types, households with wives employed in the market (either full and part time) have the lowest apparent mean intakes of ten of the twelve nutrients. Work elsewhere by the au-

thors showed that wife's employment status had a significant effect on increasing the likelihood of dietary inadequacy for several nutrients. This contrasts with findings for the United States (Adrian and Daniel), which were that wife's market work was associated with increased intake for six out of eight nutrients studied (significant for 2 nutrients). Methodological differences between the two studies may be an issue because Adrian and Daniel use household rather than per capita levels for variables, and they also have wife's employment status as exogenous.

Because there are some limitations of using expenditure data to examine nutrient availability, further analysis with more ideal data would be potentially useful, in particular including information on the foods eaten away from home. The study also indicates that U.S./Canadian comparisons would be a fruitful topic for further study, particularly given the past underutilization of the Canadian data.

Finally, regarding the policy implications: the authors are very far from suggesting that wives ought to be persuaded not to work outside the home. The results, however, do confirm the stresses borne by women and their households when women work outside the home and end up with a "double day" of work. Policies designed to help households deal with these stresses might be useful. This would be especially important for low income households where both adults work. In the food area, these policies might include augmenting existing efforts to ensure the optimal nutrient content of restaurant meals (including fast food meals, and meals eaten away from home by children) and nutrition education efforts for nutrient-dense, convenient, home food preparation techniques. In addition to policy changes, major changes in societal values affecting the division of labor within the household (such as involving men more in food purchasing and preparation) may also ease some of the stresses experienced by households where wives work outside the home, reflected in these results.

Long-Run versus Short-Run Planning Horizons and the Rangeland Stocking Rate Decision

L. Allen Torell, Kenneth S. Lyon, and E. Bruce Godfrey

Reduced future forage production, diminished range condition, and reduced animal performance have been major factors considered when setting rangeland stocking rates. The relative economic importance of diminished current period animal performance versus intertemporal forage production impacts was investigated using a dynamic optimal control model. The model is applied to yearling stocker production in eastern Colorado. Results indicate that intertemporal grazing impacts to forage production are not that important; reduced weight gain during the current period drives the economic stocking rate decision. Further, ranchers have no economic incentive as profit maximizers to continually overgraze the range.

Key words: livestock grazing, optimal control, optimal rangeland use, range economics, stocking rates.

Overgrazing can reduce future forage flows, as evidenced by the history of livestock grazing on much of the public domain (Stevens and Godfrey). Because of this, setting rangeland stocking rates is considered one of the most important grazing management decisions from the standpoint of vegetation, livestock, wildlife, and economic returns (Holechek, Pieper, and Herbel). In addition to the past common property problem (Hardin), the short-term planning horizon of livestock producers, even when property rights are assigned, is often cited as the reason for rangeland degradation (Workman, p. 52). Some argue that the overgrazing problem would be solved if ranchers would only consider the impact of current stocking decisions on future range condition and production.

L. Allen Torell is an associate professor of agricultural economics, New Mexico State University, Las Cruces; Kenneth S. Lyon is a professor, and E. Bruce Godfrey is an associate professor, Department of Economics, Utah State University, Logan.

This is Journal Article No. 1510 of the Agricultural Experiment Station, New Mexico State University.

This research derives from and extends Torell's doctoral thesis, which was supported by the Utah State University Agricultural Experiment Station. The empirical model application was conducted by William W. Riggs as a master's thesis at New Mexico State University.

The authors appreciate helpful reviews of earlier drafts by John P. Workman, Utah State University; Richard H. Hart, U.S. Department of Agriculture, ARS High Plains Grasslands Research Station; Soumen Ghosh, New Mexico State University; and the anonymous *Journal* referees.

Similar to the apparent short-term planning horizon of some ranchers, past economic stocking rate models have also been developed from a static, short-term perspective (see for example, Hart et al. 1988a,b; Hildreth and Riewe; Torell and Hart; Workman). These models are driven by falling animal performance (i.e., weight gain, calf crop, conception rates) as stocking rates increase, and the models ignore the impact of grazing on future range condition and production.

Stocking rates determined to be economically optimal over the single period may not be optimal at all when dynamic forage production impacts are considered. The relative importance of stocking rates in determining current period animal performance and the dependence of resource flows on prior use rates will determine the need for sophisticated dynamic models when making stocking rate decisions.

In this paper, a dynamic economic model that incorporates both current and future period impacts of the stocking rate decision is developed. The model can be used to investigate the optimal frequency of rangeland investments, and the investment of judicious grazing practices to extend and enhance rangeland productivity is directly considered. Similar dynamic stocking rate models have been developed by Pope and McBryde, Karp and Pope, and Rodriguez and Taylor; but our application is unique in that op-

timal stocking rates determined by the dynamic model are compared to economic stocking rate recommendations based on traditional single-period (myopic) stocking rate models. Through this comparison, the relative importance of grazing impacts to current and future period livestock production are examined and the need for more sophisticated dynamic models for stocking rate decisions is evaluated.

The economic model is developed and applied to stocker cattle operations because data were available and because this allows certain simplifications to be made. However, stocking rates for stocker cattle operations are substantially more adjustable through time in response to forage availability and cost/price variations than are cow/calf enterprises. The incentive for ranchers' to retain brood stock through drought periods and to incur short-term losses, so as to avoid the expense of buying additional brood stock at a later date, is an important consideration that may increase the motivation for cow/calf producers to overgraze.

The Traditional Single-Period Stocking Rate Model

The traditional value of marginal product model of optimal input use has been applied to the stocking rate problem by numerous authors (Hart et al. 1988a,b; Hildreth and Riewe; Riewe; Torell and Hart; Workman). Although the variable input differs, these economic evaluations start with a basic definition of input/output relationships. Most recently, stocking rate studies have standardized the grazing input to grazing pressure (GP is animal days of grazing per unit of forage) or forage allowance (animals/unit of forage) (Hart et al. 1988a, Vallentine). This standardization adjusts for grazing intensity differences as forage production varies between years because of weather and other environmental factors.

We use the basic definitions of Hart et al. (1988a) and define stocking rate (SR) as the number of stockers grazing per hectare over a grazing period of length v , and SD as the number of stocker days grazing per hectare (i.e., $SD = v \cdot SR$). GP is current period grazing pressure measured in stocker days of grazing per unit of standing herbage (H) produced (metric ton = 1,000 kilograms—kg);

$$(1) \quad GP = SD/H = v \cdot SR/H.$$

In this single-period model, herbage production

and the length of the grazing period are exogenously defined (or estimated) at the time the stocking rate decision is made. This assumed knowledge of peak standing forage production for the year would be limiting in some cases, especially when warm-season grasses predominate the range site and the majority of grass growth is not realized until well after the range is stocked.¹ At other locations, where cool-season (early growing) grasses predominate, a satisfactory estimate of expected peak standing forage crops could be made. For example, Hart found for cool season grasses growing on the High Plains of Wyoming, annual forage production had nearly peaked by the time pastures were stocked in May, with 94% of the variation of annual forage production explained by the amount of March–May precipitation.

The relationship between gain per animal per day (average daily gain, ADG) and SR is defined to be a concave function given by

$$(2) \quad ADG = f(GP(SR)),$$

with $df/dSR < 0$ and $d^2f/dSR^2 \leq 0$ over the economically relevant range of production.

The total kilograms of beef produced per hectare, as given by the production function, is defined by multiplying the number of steers grazing per hectare times their average sale weight (W_s);

$$(3) \quad b(GP(SR)) = SR \cdot W_s$$

equals kilograms of beef sold per hectare, where

$$(4) \quad W_s = [W_p + v \cdot f(GP(SR))]$$

equals stocker sale weight (kg), and W_s is determined by the stocking rate decision. For a given level of herbage production, increased stocking rates will decrease ADG and average sale weights. Average sale weight will also depend on purchase weight (W_p) and the length of the grazing period (v).

Heavier feeder cattle generally sell for less (Schroeder et al.). While sale price is determined by market forces outside the rancher's control, the rancher determines which market price to accept by the size and quality of cattle produced. This depends on the stocking rate decision such that, in addition to market forces, P_s

¹ Rodríguez and Taylor show that it would be economically advantageous to stock heavily but maintain a flexible marketing strategy and sell early if realized forage conditions were less than anticipated. This would be equivalent to adjusting v so as to maintain the optimal GP .

is a function of SR and other livestock characteristics;

$$(5) \quad P_s = P_s(W_s(GP(SR)), X),$$

where X is a vector of exogenous variables that identify relevant characteristics of the stocker cattle at time of sale (e.g., breed, frame size, health, fill, sex, muscling) and price expectations.

The rancher selling in the competitive market must choose the stocking rate that maximizes profit where, like the model of Hildreth and Riewe, profit per hectare is defined to be

$$(6) \quad \pi(GP(SR)) = P_s(W_s(GP(SR)), X) \cdot b(GP(SR)) - (P_p W_p + r) SR - a,$$

where P_p is steer purchase price (\$/kg); $P_p W_p$ is per head animal purchase cost, r is per head input factor costs (e.g., supplemental feed, vaccines, labor), which vary with the number of stockers grazing the pasture, and a is total fixed production costs, which do not vary with use rate of the pasture.

Differentiating equation (6) with respect to SR gives the standard result for optimal input use; at the optimum, the value of the marginal product (VMP) from adding another stocker to the pasture will equal the marginal factor cost (MFC) of putting it there. Considered in the first-order condition are the marginal value and marginal cost of adding the last stocker to the pasture, the negative impact to ADG of all animals in the pasture, and adjustments to expected selling price as sale weights change with stocking rate.

The solution to the myopic stocking rate model may not be optimal when dynamic impacts of current stocking rates on future forage production are considered. With a dynamic model formulation, the significant change is that stocking rate decisions during the current period directly impact forage production, potential beef production, and revenue in all future years.

A Dynamic Stocking Rate Model

In a dynamic setting, a rancher must choose the rangeland use rates that maximize the present discounted value of economic returns calculated over a multiperiod planning horizon. If rangeland improvement practices will rejuvenate the productivity of a range site depleted by the past time path of stocking rate decisions or from naturally occurring brush invasion not related to grazing, a chain of renewal cycles (range im-

provements) exists. In this case, renewal cycle S , defined as the length of time between two pasture improvements, must be chosen. If no feasible rangeland improvement practice can be implemented, the current stand of grass must be managed from now to infinity.

To model the interaction between use rates and resource flows, we follow the same procedure outlined by Stevens and Godfrey. An index of rangeland productivity at time t is defined to be $I(t)$ ($0 \leq I(t) \leq 1$).² This index is a measure of average rangeland productivity obtained with the grazing policy being evaluated, relative to average production sustainable through time under light or no grazing (\bar{H}).

The average rangeland productivity index changes through time, depending on the grazing history of the pasture. If relatively heavy stocking occurred last year, the herbage production index this year may be reduced. Movement of the index is defined to be a function of the previous period's GP , the previous period's index value, and additional productivity declines not related to grazing use rates (e.g., naturally occurring brush invasion and diminished site productivity).

Average herbage production at a point in time is given by the equation

$$(7) \quad H(t) = I(t)\bar{H},$$

with past impacts of grazing captured by $I(t)$.

By differentiating equation (7), the equation of motion for the state variable $H(t)$ is given by a differential equation of the form

$$(8) \quad dH/dt = dI/dt \cdot \bar{H} = \Phi(GP(SR(t)), H(t), t).$$

With the initial condition that at the start of the planning period, $I(t_0) = 1$ or $H(t_0) = \bar{H}$, equation (8) defines the time path of annual average herbage production, depending on the solution set to $SR(t)$.

Average herbage production would be expected to decline through time as brush invades the pasture. Further, heavier stocking rates would be expected to accelerate the rate of brush invasion and the decline in rangeland productivity; this grazing interaction is captured in the dynamic model. $H(t)$ is an endogenously determined state variable, and the time path of herbage pro-

² Normally, the maximum index value might be set at one, implying light or no grazing yields maximum herbage production. However, it is possible that with alternative grazing systems a heavier stocking rate would yield higher herbage production through time and thus give an index greater than one.

duction depends on the stocking rate decisions made over the planning period.

Random fluctuations in weather conditions, especially rainfall, will cause annual deviations from the herbage production defined by equation (7), but these deviations will be offsetting on average. The computed average herbage production from equation (7) is the expected herbage production at that point if random variation in herbage production is normally distributed about some mean production level.³ This mean production level will change depending on stocking rate decisions, and this changing average production is tracked in the dynamic model.

The annual profit function of equation (6) is now altered to include herbage production:

$$(9) \quad \pi(GP(SR(t), H(t))) \\ = P_s(W_s(GP(SR(t), H(t))), X) \\ \cdot b(GP(SR(t), H(t))) \\ - (P_p W_p + r)SR(t) - a.$$

The profit-maximizing rancher would maximize the discounted net present value (NPV) from grazing over all future years. The wealth from a single grass stand rotation is given by

$$(10) \quad C(1) = \int_{t_0}^S \pi(GP(SR(t), H(t)))e^{-\rho t} dt - K(0),$$

where ρ is the discount rate used to discount future returns, t is the year under consideration, and $K(0)$ is the cost of stand rejuvenation implemented at time 0 (e.g., brush control, reseed, pasture reestablishment).

The integral is defined to start at time t_0 ($0 \leq t_0 < S$), which reflects the specified grazing deferment policy associated with grass stand rejuvenation. Assuming all rotations are alike, following Perrin's replacement model, the wealth from all future rotations is given by

$$(11) \quad C(\infty) = A(S)C(1),$$

where $A(S) = 1/(1 - e^{-\rho S})$ = infinite series factor, the present value of a perpetual annuity received every S years.

The objective functional given by $C(\infty)$ is

maximized subject to the initial stock of herbage available for grazing during period t_0 ($H(t_0) = \bar{H}$), and the law of motion for the system as given by equation (8). If rejuvenation of the pasture is possible, the optimal rotation period (S) must also be chosen. If rejuvenation is not possible, such that S is set to ∞ , maximizing $C(1)$ or $C(\infty)$ is equivalent.

Using theorem 1 of Long and Vausden, the Hamiltonian for the maximization problem can be written as

$$(12) \quad H = A(S)[\pi(GP(SR(t), H(t)))e^{-\rho t} - K] \\ + \omega \cdot \Phi(GP(SR(t), H(t))).$$

Given equation (8), this is an optimal control problem, where S is a control parameter, $SR(t)$ is the control variable (function), $H(t)$ is the state variable, and ω is the costate variable defining the shadow value of herbage at each point in time.

In both the static and dynamic model, grazing pressure directly impacts current period beef production through grazing pressure impacts to ADG. However, in the dynamic model, the effect of stocking intensity in previous years is captured through its impact on herbage production during the current period. Profits at a point in time are a function of $SR(t)$ and the amount of herbage at that point. Average herbage production evolves from starting point \bar{H} , depending on how heavily the pasture is grazed. Two implicit assumptions are (a) pasture rejuvenation (e.g., killing the brush, reseeding) followed by the specified deferment policy will result in the return of grass production to the beginning level given by \bar{H} , and (b) each treatment cycle is identical.

Similar to the replacement criterion developed by Perrin and by Chavas, Kliebenstein, and Crenshaw, the optimal rotation period is extended to the point where the rent during the S th period is equal to the interest that could be earned on the wealth obtained by optimally utilizing the forage over the S -year rotation period.

Model Application

The maximization problem so far has been represented with continuous-time variables to allow simpler algebraic analysis. We illustrate a discrete time optimal control formulation of the dynamic problem below and use this empirical model to determine the time path of rangeland productivity that would result under profit-max-

³ Using a similar dynamic stocking rate model and simulated data from the SPUR rangeland simulation model (Wight), Torelli investigated how weather variations affected the dynamic stocking rate decision. Optimal GP and the time path of herbage production were found to be similar over a wide range of alternative weather patterns.

imizing behavior by ranchers. For the dynamic model, we solve for the optimal time path of $SR(t)$, for a number of rotation lengths, then select the grass stand replacement age that is optimal, as indicated by the maximum objective functional value $[C(\infty)]$. Solution to the empirical model was obtained using the MINOS nonlinear programming algorithm (Murtaugh and Saunders).

To evaluate differences in optimal use rates and in optimal rangeland productivity through time, the traditional single-period (myopic) model was iteratively solved for similar price/cost situations. This was done by determining the myopic optimal stocking rate for year 1 and then using the estimated equation of motion to define average herbage production that would result in year 2 with this SR . The optimal stocking rate for year 2 was then calculated and the procedure was repeated over the planning horizon. A similar procedure, but with dynamic interactions considered in the optimization, was also used for the dynamic model. This comparison of the myopic and dynamic solutions indicates the importance of developing more complex dynamic models and provides an evaluation of diverging trends in rangeland productivity when the future is not considered in stocking rate decisions.

The Study Site

The empirical analysis uses data from a long-term grazing study conducted in eastern Colorado (see Sims, Dahl, and Denham for a complete description of the grazing trial methods and results). This Colorado example is one of the few grazing studies with adequate design and length to quantify the long-term impacts of grazing to livestock and forage production needed for economic analysis.

The Colorado grazing study was conducted over fifteen years, from 1955 through 1969, with both livestock and forage response to grazing treatments measured during selected years. The study site was in the central Great Plains, in the northeastern Colorado sandhills. Average annual precipitation over the study period was about 38 centimeters (15 inches). The distribution of rainfall was normally distributed, with an equal number of years below and above the reported average. About 73% of the precipitation occurred during the active growing season between 1 April and 31 August.

The vegetation was heterogenous with major forage species of blue grama (*Bouteloua gra-*

cilis), prairie sandreed (*Calamovilfa longifolia*), and needle-and-throat (*Stipa comata*). The primary invading brush species was sand sagebrush (*Artemisia filifolia*).

Three continuous season-long grazing treatments were implemented during 1955, with 4 hectares allowed per grazing steer for the defined light stocking rate, 2 hectares for the moderate stocking rate, and 1.3 hectares for the heavy rate. The grazing season was 150 days long, from about 1 May to 30 September. Livestock response data were recorded from 1955 through 1965, and herbage production data were recorded from 1957 through 1968. Average herbage production measured over the twelve years was 1,728, 1,485, and 1,311 kilograms per hectare under light, moderate, and heavy grazing treatments, respectively.

Table 1 shows the herbage production and percent forage utilization reported for each of the three stocking rates. Also shown is the grazing pressure calculated for each year of the grazing trial, based on other data reported by Sims, Dahl, and Denham. The data reported in table 1, along with other livestock response data reported in the Colorado grazing study were used to estimate the equations of the optimization model.

Rangeland productivity was negatively impacted through time by increased grazing pressure. In fact, the Colorado grazing study found, for this range site, that any rangeland productivity deterioration was related directly to grazing pressure.⁴ Rangeland productivity increased slightly under the light grazing treatment, especially during the first seven years of the study. It decreased under the heavy use rate and remained relatively constant at the moderate rate. By 1965, when the light grazing treatment was discontinued, herbage production under moderate grazing averaged about 94% that of the light treatment, compared to 82% under the heavy treatment.

In addition to reduced herbage production, increased grazing intensity had adverse, but not major, impacts to the range resource; it de-

⁴ This result is in contrast to the range replacement model of Burt (1971), where grazing was assumed to have no significant impact on the rate of brush encroachment and productivity decline. In response to criticism on this assumption, Burt (1972) stated that there is little empirical evidence to support or refute the importance of grazing to the retreatment problem. We would agree with Burt's observation for the piñon-juniper problem he addressed; essentially, no empirical work has been done on this problem since Burt's paper was written. As a result, grazing impacts to future resource flows are largely unquantified and undoubtedly range site and species specific.

Table 1. Herbage Production (*H*), Grazing Pressure (*GP*) and Forage Utilization Under Three Stocking Rates, 1957–68

Year	Stocking Rate

^a Herbage production under moderate grazing divided by herbage production under light grazing.

^b Herbage production under heavy grazing divided by herbage production under light grazing.

creased the amount of desirable cool season grasses, diminished range condition, and increased the density and overstory of sand sagebrush.

As in many other grazing studies, average daily gain and gain per head were lowest under heavy stocking rates. Holechek, Pieper, and Herbel attribute this decline in livestock performance to reduced forage intake and diet quality. Decreased forage availability reduces animal selectivity and forces grazing animals to select diets lower in quality. It also forces animals to spend more energy on foraging activities that could otherwise go into production.

Beef production per hectare is determined by the weight of the animals and the number of animals in the pasture. In the Colorado grazing study, beef produced per unit land area was highest under the heaviest stocking rate for every year of the study.

Model Specification

Using data from Sims, Dahl, and Denham, various model equations and relationships, including the production function and equation of motion, were estimated using ordinary least squares regression. The beef price model of Schroeder et al. was used to determine selling price as a function of the endogenously determined sale weight. In addition, the linear relationship between *GP* and forage utilization was estimated

so as to relate our model results to the standard stocking rate prescriptions made by range scientists using percent forage utilization as an indicator of proper use.⁵ Estimated regression equations are shown in table 2.

Beef production function. Several different functional forms of the average daily gain function have been specified in past grazing research, but a linear equation has been the most common specification and adequately defines *ADG* response to grazing pressures (Bransby et al.; Hart et al. 1988a,b; Hildreth and Riewe). With a linear *ADG* function, equations (3) and (4) imply a quadratic production function.

Equation of motion. The equation of motion was estimated as a linear first-order difference equation. We tried a number of different functional forms of the equation, but a linear equation seemed to fit best. As shown in table 1, there was no trend of herbage production that was not associated with the level of grazing use. Under light grazing, herbage production, range condition and the amount of brush in the pasture was nearly constant through time.

⁵ Current stocking rate recommendations, for example, are to maintain rangeland productivity by harvesting no more than 30% to 60% of available forage, depending on range type (Holechek, Pieper, and Herbel, p. 190).

Table 2. Selected Equations of the Stocking Rate Models

Average daily gain (kg/head/day) ^a		
$ADG = f(GP_t) = 0.82 - 0.0029 \cdot GP_t$		
Sale weight (kg/head) ^{a,b}		
$W_s = [W_p + v \cdot ADG] = 338 - 0.436 \cdot GP_t$		
Livestock gain per hectare (kg/ha) ^b		
Gain = $SR_t \cdot v \cdot ADG = SR_t(123 - 0.436 \cdot GP_t)$	(6.2673) ^c (0.0845)	$R^2 = 0.99$
Beef production per hectare ^b		
$b(GP(SR)) = SR_t \cdot W_s = SR_t(338 - 0.436 \cdot GP_t)$		
Equation of motion		
$I_t = 0.4343 + 0.5824 \cdot I_{t-1} - 0.00136 \cdot GP_{t-1}$	(0.1222) (0.1169) (0.0005)	$R^2 = 0.72$
$H_t = I_t \cdot \bar{H}$		
Percent forage utilization		
$U_t = 17.8008 + 0.5220 \cdot GP_t$	(3.582) (0.0628)	$R^2 = 0.73$
Beef prices ^d		
$P_p = 1.5064 + 0.465 \cdot Fut_{spring} - 0.00348 \cdot W_p + 0.000002 \cdot W_p^2$		
$P_s = 0.5626 + 0.314 \cdot Fut_{fall} + 0.00238 \cdot W_s - 0.000004 \cdot W_s^2$		

^a The equation for livestock gain per hectare was estimated directly from data presented by Sims, Dahl, and Denham. The *ADG*, sale weight, and beef production per hectare functions were algebraically estimated from this equation.

^b Assumptions: $W_p = 215$ kg, and $v = 150$ days.

^c The standard error of the estimate is presented in parentheses.

^d Reduced equations from Schroeder et al. with the livestock characteristics defined.

The herbage production index was estimated as

$$(13) \quad I_t = \alpha_0 + \alpha_1 I_{t-1} + \alpha_2 GP_{t-1}.$$

Then, I_t was multiplied by $\bar{H} = 1,728$ kilograms per hectare, the average herbage production under light grazing (table 1), to give

$$(14) \quad H_t = (\alpha_0 \bar{H} + \alpha_1 H_{t-1} + \alpha_2 \bar{H} \cdot GP_{t-1}).$$

In solving the optimization problem, the NPV of annual profits was maximized subject to constraints defining the dynamics of the system using equation (14). The constraint set was defined to be

$$(15) \quad \begin{matrix} A & X & = & b \end{matrix}$$

$$\begin{bmatrix} 1 & 0 & 0 & 0 & \dots & 0 & 0 & 0 & \dots & 0 \\ -\alpha_1 & 1 & 0 & 0 & \dots & 0 & -\alpha_2 \bar{H} & 0 & \dots & 0 \\ 0 & -\alpha_1 & 1 & 0 & \dots & 0 & 0 & -\alpha_2 \bar{H} & \dots & 0 \\ \vdots & & & & & \vdots & & & & \vdots \\ 0 & 0 & 0 & 0 & \dots & -\alpha_1 & 0 & 0 & \dots & -\alpha_2 \bar{H} \end{bmatrix} \begin{bmatrix} H_{t_0+1} \\ H_{t_0+2} \\ H_{t_0+3} \\ \vdots \\ H_{t_0+S} \\ GP_{t_0+1} \\ GP_{t_0+2} \\ \vdots \\ GP_{t_0+S} \end{bmatrix} = \begin{bmatrix} \bar{H} \\ \alpha_0 \bar{H} \\ \alpha_0 \bar{H} \\ \vdots \\ \alpha_0 \bar{H} \end{bmatrix}$$

⁶ If range site productivity declined over time from additional naturally occurring brush invasion and maturation that was not related to grazing, equation (13) could be specified with an additional time variable such as $I_t = \alpha_0 + \alpha_1 I_{t-1} + \alpha_2 GP_{t-1} + \alpha_3 t$, ($\alpha_3 < 0$).

Beef price function. Depending on livestock characteristics at the time of purchase and sale, the beef price model of Schroeder et al. can be used to estimate purchase and sale prices for feeder cattle. As shown by these authors, heavier feeder steers generally sell for less per kilogram. Thus, an increased stocking rate would be expected to increase sale price.

The Schroeder et al. model uses observed futures market prices to form price expectations. In this application, the futures prices in the fall (Fut_{fall} , on 1 October) and spring (Fut_{spring} , on 1

May) over the period 1979 to 1988 were used. This ten-year cycle of futures prices was repeated to estimate expected purchase and sale

prices of steers over a specified forty-year planning horizon.⁷

We assumed that uniform lots of healthy, mixed breed, medium sized cattle would be bought and sold. These assumptions result in reduced parameter price equations, with only the exogenously defined futures price and endogenous livestock sale weight as explanatory variables (table 2). The purchase price of stockers was exogenously defined with specification of the spring futures price and an assumed 215-kilogram purchase weight.

Table 3 shows the ten years of estimated beef prices used in the analysis, assuming an average 310-kilogram sale weight of steers.⁸ The smaller the price discount (price margin) between purchase and sale, the more favorable production is for yearling stocker operators. Of the ten years considered in setting expected beef prices, 1979 was the worst price year (widest price margin) and 1980, 1986, and 1987 were the best price years for yearling production.

Other model parameters. Using cost and return estimates prepared for yearling stocker operators in Kansas (McReynolds and Barnaby) and in New Mexico (Torell, Williams, and Brockman), variable production expenses (r),

including salt and minerals, fuel and repairs, veterinary and medicine, labor, marketing, and miscellaneous expenses, were estimated to be \$55 per head over the 150-day grazing season. Fixed production expenses (a) were estimated to be \$18 per hectare including a return to operator labor and management, such that the objective function value represents a discounted return to land and improvements. The return stream was discounted at a 7% rate of interest (ρ). Other computer runs were made to evaluate the sensitivity of the solution to the discount rate.

To analyze differences in the time path of rangeland productivity under both the single-period and dynamic models, a forty-year planning period with two years of deferment ($t_0 = 2$) was considered. Treatment cost (K) was \$41 per hectare, the average cost for control of sagebrush using tebuthiuron pellets (McDaniel et al.). Additional computer runs were also made to see how cost of treatment affected the optimal re-treatment strategy.

Application Results

Optimal stocking rates. The optimal stocking rate varies from year to year (fig. 1). In good price years, with a relatively small price discount for heavier cattle, like 1980, 1986, and 1987 (table 3), the optimal stocking rate is nearly twice that of unfavorable price years like 1979 when the price discount is large. Standard stocking rate recommendations often recognize that grazing use rates should vary from year to year, de-

⁷ With a positive discount rate, numerical solution could not be obtained for over a 40-year grazing rotation; thus, this was the maximum rotation considered.

⁸ In the actual analysis, purchase weight was constant at 215 kg, but sale weight varied depending on the optimal stocking rate decision.

Table 3. Beef Prices Used in the Economic Analysis

Price Year	Year in the Analysis	Futures Price		Estimated Price		Price Discount
		Spring	Fall	Purchase	Sale	
----- (\$/kg) -----						
1979	1, 11, 21, 31	2.01	1.83	1.79	1.44	-0.35
1980	2, 12, 22, 32	1.50	1.65	1.55	1.39	-0.16
1981	3, 13, 23, 33	1.57	1.46	1.59	1.32	-0.27
1982	4, 14, 24, 34	1.48	1.46	1.54	1.33	-0.21
1983	5, 15, 25, 35	1.43	1.30	1.52	1.27	-0.25
1984	6, 16, 26, 36	1.41	1.43	1.51	1.32	-0.19
1985	7, 17, 27, 37	1.43	1.39	1.52	1.30	-0.22
1986	8, 18, 28, 38	1.17	1.37	1.40	1.30	-0.10
1987	9, 19, 29, 39	1.54	1.73	1.57	1.41	-0.16
1988	10, 20, 30, 40	1.74	1.70	1.67	1.40	-0.27

Note: Specification of the Schroeder et al. price model was with a purchase weight of 215 kg, variable sale weight depending on the stocking rate decision, 50-head lot size, healthy fleshy condition, mixed horns and breeds, shrunk fill, medium muscling, medium upper and lower frame, purchased during 2nd quarter at market 5, sold during 4th quarter at market 5 and with future prices (\$/kg) as specified above.

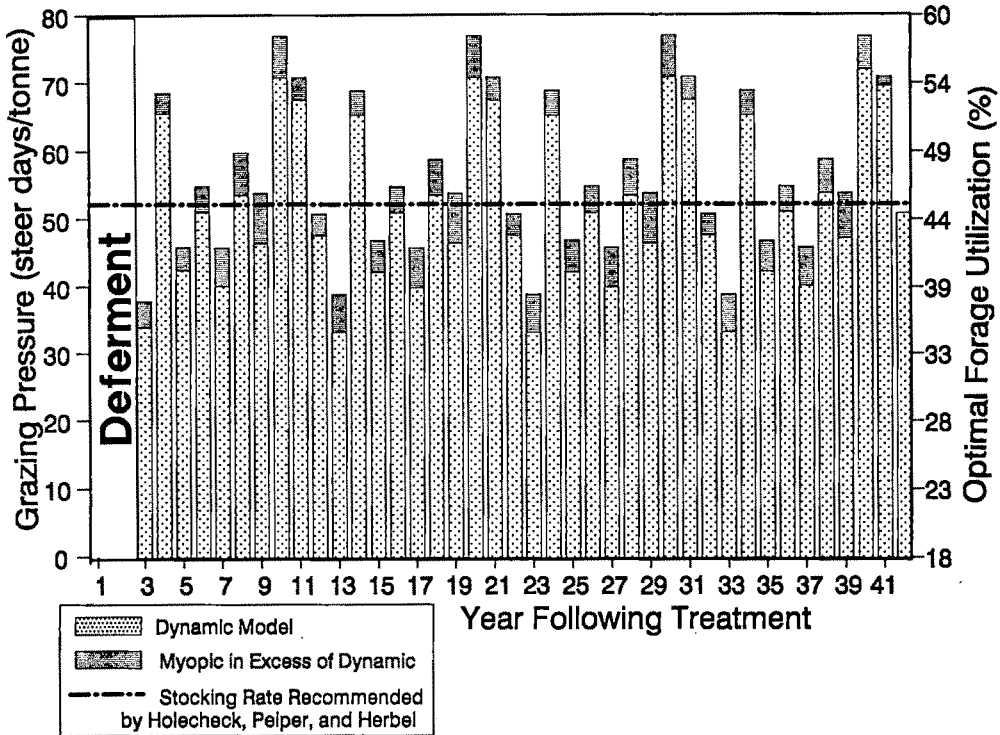

Figure 1. Time path of optimal grazing pressure and forage utilization

pending on forage production, but variation due to economic conditions is rarely recognized.⁹

In most years, economically optimal *GP* would be near that realized under the moderate stocking rate definition of the Colorado grazing study (table 1). Defined heavy use rates would be optimal during good price years.

The current stocking rate recommendation for this midgrass prairie site is to utilize 45% of available forage (Holechek, Pieper, and Herbel, p. 190). This implies a constant *GP* of fifty-two steer days per metric ton of forage. The recommendation, based largely on noneconomic factors, is remarkably close to the average economic optimal use rate shown in figure 1. Adjusting stocking rates to economic conditions is important, however. By adjusting stocking rates up and down depending on economic conditions, the objective function value was increased by 24%, from minus \$63 per hectare with the

constant 45% utilization rule to minus \$48 per hectare with flexible, economically optimal stocking rates.

Optimal stocking rates determined by the dynamic and single-period (myopic) models were not greatly different. As expected, when impacts to future forage production were included in the stocking rate decision, economically optimal stocking rates were decreased, but only slightly. This implies, for this midgrass prairie range site, that the impact of grazing pressure on current period animal performance drives the economic stocking rate decision. This is different than the results reported by Pope and McBryde, where diminished rangeland productivity drove the economic stocking rate decision.

As the planning period draws to a close, the difference between optimal stocking rates defined by the dynamic and myopic stocking rate models is reduced until the final year, when the two rates are equal. This occurs because there is no additional future value to remaining forage; i.e., the opportunity cost of increased grazing is zero because the grass stand will be rejuvenated next year.

⁹ Holechek, Pieper, and Herbel (p. 186) recognize four basic strategies that producers might select: (1) stock conservatively so that the range is not overstocked, (2) stock at a high rate commensurate with forage availability during favorable years, (3) stock at the average, and (4) vary stocking to meet forage supplies for each year.

Optimal rangeland productivity. Corresponding to the fluctuations in optimal stocking rates, average herbage production varies optimally through time after reaching a long-term level of production equilibrium (fig. 2), similar to that found under moderate use rates in the Colorado grazing study (table 1). Further, as shown with other applications in natural resource economics (Samuelson, Fisher), producing at a maximum sustainable yield would not be economically optimal. Peak forage production was not maintained under profit-maximizing stocking rates with either the myopic or dynamic models. Rangeland productivity was not devastated either. After an initial drop in average herbage production, optimal rangeland production declined to about 1,500 kilograms per hectare under the dynamic model and 1,450 kilograms per hectare for the myopic model. Implications are that maintaining maximum sustainable grass yield and range condition, a primary goal in range management, is unobtainable, given the profit motive of ranchers. But, for this range site, the profit motive will not ruin the range either.

Net present value. By reducing stocking rates and foregoing revenue in the early years of the planning period, revenue in future years was increased only slightly for the dynamic model ($-\$43/\text{ha}$ for the dynamic model versus $-\$49.33/\text{ha}$ for the myopic model). As indicated by the negative objective function values, alternative resource uses may be expected over the long term. Annual returns to land and improvements were only positive with the 1980, 1984, 1986, and 1987 beef price situations. Variable production expenses were covered in all years. Price margins between yearling purchase and sale have widened in recent years, and

the profit potential for yearling stocker operations on rangeland, relative to cow/calf and sheep ranches, has diminished (Torell, Williams, and Brockman).

Optimal retreatment schedule. Given a $\$41$ per hectare treatment cost, plus two years of grazing deferment, there is no need for retreatment on the Colorado study site. Model results indicate grass productivity would be maintained by grazing at economically optimal stocking rates. Realistic beef prices faced by livestock producers will cause economically optimal stocking rates to lie below levels that would significantly deteriorate rangeland productivity. In this application, no additional investment through significantly reduced grazing use rates or rangeland brush control treatments is needed or economically justified.

By extending the grass rotation from every seventeen years to every twenty-two years, the value of the objective function increased from $-\$73$ per hectare to $-\$58$ per hectare. Increasing the rotation by an additional ten years (32-year rotation) decreased the loss still further to $-\$51$ per hectare. With forty years of grazing use before retreatment, the objective function value was reduced slightly more to $-\$48$ per hectare. If a rancher started with the Colorado range site already at peak forage production, such that no initial treatment and deferment were necessary, managed the site over an infinite planning horizon, and used economically optimal stocking rates every year, the specified costs and prices considered in the analysis would indicate a nearly breakeven investment. In this case, the objective function value (return to land and improvements) would be $-\$5$ per hectare.

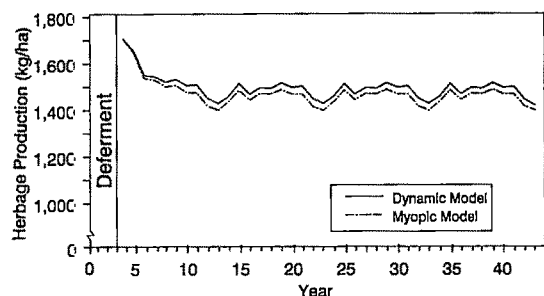

Figure 2. Time path of optimal herbage production

Sensitivity analyses. As shown in figure 1, optimal GP was sensitive to changes in expected beef prices and annual production costs. This was true of both the dynamic and myopic models. Additional computer runs were made to see how sensitive the optimal solution was to rangeland treatment costs (K) and discount rate (ρ). In general, the solution was not significantly affected by changes in either of these parameters.

As shown by Perrin, increasing the discount rate generally results in an earlier optimum replacement age, as occurred in this application. Because the model would not solve for more than

a forty-year planning period, we could not establish an exact optimal time for replacement. Empirical results indicated, however, as the discount rate increased from 7% to the unrealistic level of 30%, that the optimal grazing use rate increased by about two steer days per metric ton of forage, implying a faster use rate and more rapid replacement. This was an insignificant difference because a two-unit change in *GP* would not even be measurable.

The value of the objective function was increased with an increase in discount rate. Increasing the discount factor from 7% to 14% increased the objective function value from -\$48 per hectare to -\$44.91 per hectare because future losses became less important in present value terms.

Optimal stocking rates were not affected by the cost of the rangeland improvement. Similarly, the optimal retreatment schedule was insensitive to treatment cost, except at unrealistically low levels. When the treatment cost was greatly reduced, from \$41 per hectare to less than \$5 per hectare, the optimal replacement cycle was every four years (plus the 2 years of deferment). Above this cost level, optimal replacement stayed at the forty-year cycle found with the base run. This is because little would be gained from implementing a range improvement as implied by the equation system defined in the Colorado application. As shown in figure 2, by practicing economically optimal stocking rates, herbage production would only decline by about 200 kilograms per hectare, and this would occur within five years.

Model Limitations

The dynamic stocking rate model developed here is deterministic with the assumption that at the time the stocking rate decision is made a rancher can accurately predict prices, costs, and forage conditions. Stochastic weather variations are not directly considered in the stocking rate decision; the time path of average rangeland productivity defines the intertemporal dynamics of the model. This procedure is appropriate for the yearling stocker operations considered in the model application. This type of livestock operation has a considerable marketing flexibility and can annually adjust the number of head purchased, depending on both economic and forage conditions. Our results show that a yearling operator should carefully consider expected economic and

forage conditions for the year and set stocking rates accordingly.¹⁰ Furthermore, the results indicate that little if any thought need be given to what the stocking rate decision will do to forage production in future years.

The stocking rate decision is more complicated when brood stock must be maintained between years. In this case, future weather patterns are an important consideration. A major cost will be incurred in selling and buying brood stock or in purchasing supplemental feed if stocking rates are set too low or high relative to realized forage production. Unlike the yearling stocker operator, cow/calf and sheep ranchers must make long-term stocking rate decisions. In this case, planning stocking rates based on the average forage production expected under alternative stocking rates may not be appropriate.

Concluding Comments

As noted by Bromley, an important grazing interaction is the impact of grazing on future rangeland productivity. This is universally believed, as evident by the rationale given for recommending desirable stocking rates (Holechek, Pieper, and Herbel; Stoddart, Smith, and Box). However, results of this study indicate that intertemporal grazing impacts to forage production may not be that important after all. Rather, our results show that dependence of current period animal performance on stocking rate is the key. Further, the model results show that ranchers have no economic incentive as profit maximizers to overgraze continually. We found, for a Colorado study site, with realistic expectations of beef prices and production costs, falling animal performance will set profit-maximizing stocking rates well below those levels that will severely deteriorate the rangeland resource. Similarly, Torell also found current period animal production impacts to limit the motivation to overgraze the range. Thus, like Workman (p. 52), we conclude that historic overgrazing can be blamed on ignorance and overoptimism about rangeland carrying capacities, but this overgrazing occurs in spite of the profit motive not because of it.

Our results, (a) animal performance driving the economic stocking rate decision and (b) no

¹⁰ If warm-season grasses that mature late in the season predominate the range site, then the uncertainty about forage production this year will be an important consideration (Rodriguez and Taylor).

economic incentive to continually overgraze the range, are not universally true. As a counter example, Pope and McBryde developed a dynamic stocking rate model for cow/calf producers in south Texas. They conclude, "if economically viable and ecologically sound range improvement treatments are available, a range management strategy that systematically overstocks and periodically applies treatments would be more profitable" (p. 167). Either result may be valid, depending on type of livestock grazed, the cost of feasible rangeland improvements, and the range site under consideration.

The idea that animal performance impacts from grazing can be the most important consideration in stocking rate decisions is a new idea for most people. The implications for management and research are many. Most important, if dynamic impacts of grazing to rangeland productivity are small relative to current period production impacts, this implies the standard economic model of optimal input use can satisfactorily be used to make nearly optimal stocking rate decisions without the more complicated modeling of dynamic interactions. More sophisticated models are not always needed.

Testing for Consistent Aggregation

Robert G. Chambers and Rulon D. Pope

This paper designs workable empirical procedures for testing or imposing supply (demand)-price aggregators. Only single-equation methods are considered to shift the focus from any particular optimizing paradigm toward the necessities for correctly tabulating firm-level supplies (demands) and aggregate supply (demand). Both macro- and micro-level tests for consistent aggregation are developed. And constructive rules for aggregation based upon empirically observed micro behavior are provided in tabular form. Empirical tests reveal no support for the aggregate price most commonly reported by USDA. The constructive rules are then used to develop a new wheat-price index consistent with supply aggregation.

Key words: aggregate demand, aggregate supply, exact aggregation, price indexes.

A substantial literature has evolved on testing for the existence and form of quantity or price aggregates (e.g., Weaver, Shumway, Ball, Chavas and Cox). These tests generally rely on separability restrictions and aggregates are formed (horizontally) either across distinct commodities (livestock, grains, etc.) or commodity prices. Dual tests based on profit, cost, or expenditure functions search for the existence of aggregate prices, while primal tests search for the existence of quantity aggregates. Under suitably strong assumptions (weak homothetic separability) dual and primal tests are equivalent.

A closely related body of literature focuses on the construction of aggregates (vertically) over individual consumers and producers (e.g., Muellbauer; Nichols; Gorman 1953, 1968; Stoker; Jorgenson, Lau, and Stoker; Antle; Chambers). This literature's motivation typically is the construction of an aggregate income, output, or capital index to be used in aggregate demand, cost, or profit systems. This approach, usually referred to as exact aggregation, is nonparametric in a statistical sense because it aggregates any income distribution. Typical of the questions asked by this approach is: "If per capita income is used in aggregate demand functions and if aggregate demand is the sum of individual demands, what form must the micro and macro demands take?" (Gorman 1953). The Gorman

polar form (GPF) is the answer. The almost ideal demand system (AIDS), a special case of Muellbauer's PIGLOG system, also aggregates consistently using Muellbauer's approach to aggregation. Numerous papers have either tested for or assumed exact aggregation using the Muellbauer approach (Deaton and Muellbauer; Nichols; Jorgenson, Lau, and Stoker; Blanciforti and Green; Eales and Unnevehr; Green and Alston).

Another empirical reality confronting agricultural economists is that not only incomes but prices also typically vary across economic agents. Heterogenous or disperse prices, while hard to explain in terms of simple neoclassical theory, are a fact of life. They can occur because of quality, timing, and spatial differences, government programs (e.g., nonrecourse loan rates are specified on a county basis), regulations, and uncertainty (heterogenous expectations). As just one example, empirical analysis consistently reveals that state-level prices of land, labor, and outputs are not nearly colinear across states (Robison, Lins, and VenKataraman; Gould and Saupe).

All aggregate supply and demand functions must inevitably deal with this reality even though to some it may contradict the usual predictions of perfect competition. The price of wheat, for example, can differ across individuals or other economic entities because of all of the above factors and still be consistent with price-taking behavior by wheat growers. To be sure, prices of different wheat "qualities" at different points in space or time are not entirely independent.

Robert G. Chambers is a professor, Department of Agricultural and Resource Economics, University of Maryland; Rulon D. Pope is a professor, Department of Economics, Brigham Young University.

But, just as certainly, examination of the data and the well-known fact of basis variations reveals that correlations across these different qualities are not nearly one. For these reasons, U.S. Department of Agriculture (USDA) price indexes must (and do) aggregate spatially and intertemporally in order to report the U.S. annual average price of a commodity. Nowhere is this more apparent than in the season average prices reported in the USDA publication *Agricultural Statistics* which weight state prices by quantities sold and include allowances for unredeemed loans and government purchases at state average loan rates (which, if applicable, are administered and not competitive prices).

This paper designs workable empirical procedures for testing or imposing supply-price aggregators which capture accurately the information that aggregate analyses are trying to uncover. Unlike Deaton and Muellbauer, only single-equation problems are studied. This specification shifts the focus away from any particular optimizing paradigm toward the necessities of correctly tabulating firm-level demands and supplies. Thus, the approach is robust to various optimization paradigms. But the single-equation approach is also adopted for two other reasons. First, it avoids the negativism associated with aggregation of systems (Pope and Chambers). Second, most applied work in agricultural economics does not employ systems-type restrictions; therefore, the methods and results here should have wide applicability.

The approach enables researchers to delineate the class of supply or demand functions consistent with the actual aggregate price indexes employed. One can then test for consistent aggregation by testing whether the implied form is appropriate. Both macro and micro tests are developed. Although some of the analysis is quite general, particular attention is paid to the two most commonly published producer price indexes, the simple and weighted averages.

In what follows, we first motivate the need for testing by illustrating the effects of using a Cobb-Douglas supply or demand function and either of the two most commonly published price indexes. The third section generalizes the above examples and provides constructive rules for consistent aggregation. The fourth section develops and applies empirical tests for consistent aggregation. Significantly, we find no empirical support for the state-level technology implied by presently calculated U.S. season average wheat prices. We propose and calculate an alternative

price index which is consistent with aggregation. The fifth section concludes. Although for illustrative purposes our discussion is solely in terms of producer models, the results apply directly to the consumer case.

Common Agricultural Price Aggregation and the Cobb-Douglas: An Example

The most common aggregate prices used by agricultural economists are simple averages or weighted averages. Prices reported in such familiar sources as *Agricultural Statistics*, *Agricultural Prices*, or the *Survey of Current Business* tend to be measured in this way. For example, *Agricultural Prices* reports commodity prices received by farmers by states on a monthly basis. These prices usually are "estimates of average prices received for all of the commodity sold during the entire month." Thus, the price-aggregation procedure is simple averaging. This same publication, as well as *Agricultural Statistics*, also reports annual U.S. season average prices for many commodities. These U.S. season average prices are computed by weighting "state season average prices by the estimated quantity sold in each state." Here the aggregation procedure is weighted averaging. (We refer to this particular weighted average as the Laspeyres in what follows.) This section briefly considers the implications of using these two price aggregation schemes in Cobb-Douglas supply-response models.

Consider the price-aggregation problem: The goal is to relate aggregate supply, Y (the sum of firm supplies), econometrically to the average industry price, $\bar{P} = 1/m \sum_{j=1}^m p_j$ (p_j is the price facing the j th firm) and a vector of input prices, w , which are assumed to be constant across all firms.

To do so, the researcher first specifies an aggregate supply function which we denote by $G(\bar{P}, w)$. Then using data on Y , \bar{P} , and w , the parameters of G are estimated. For many agricultural applications, G might be chosen as Cobb-Douglas, $G \equiv A\bar{P} w^{-a}$. For notational simplicity, assume w is a scalar.

A basic question is: Is this procedure consistent in the sense that G accurately represents the sum of firm supplies over all m firms? Differentiate both sides of the aggregate supply relationship ($Y = G(\bar{P}, w)$) with respect to p_i and p_j ($j \neq i$) using the definition of Y , G , and \bar{P} to

find that a necessary condition for a positive answer is

$$(1) \quad \frac{\frac{\partial G}{\partial \bar{P}} \frac{\partial \bar{P}}{\partial p_i}}{\frac{\partial G}{\partial \bar{P}} \frac{\partial \bar{P}}{\partial p_j}} = \frac{\frac{\partial \bar{P}}{\partial p_i}}{\frac{\partial \bar{P}}{\partial p_j}} = \frac{\partial Y / \partial p_i}{\partial Y / \partial p_j} = \frac{\partial y_i / \partial p_i}{\partial y_j / \partial p_j} \quad \text{for all } i, j = 1, \dots, m.$$

Because \bar{P} is the simple average, expression (1) reduces to

$$\frac{\frac{\partial \bar{P}}{\partial p_i}}{\frac{\partial \bar{P}}{\partial p_j}} = 1 = \frac{\partial y_i / \partial p_i}{\partial y_j / \partial p_j} \quad \text{for all } i, j = 1, \dots, m.$$

Supply slopes must be equal for all firms for aggregation to be consistent. Because each such slope can depend only upon p_i and w (firm supply depends only on the prices it faces), these slopes must be independent of the firm and hence depend only on w . Integrating with respect to p_i yields

$$y_i = \alpha_i(w) + \beta(w)p_i \quad i = 1, \dots, m.$$

That is, firm-level supplies must be linear in own price. Rejection of this form implies that mean price cannot consistently aggregate supplies. Summing shows that aggregate supply is also linear:

$$Y \equiv \sum_{i=1}^m y_i = \sum_{i=1}^m \alpha_i(w) + \beta(w) \sum_{i=1}^m p_i = \alpha(w) + \beta(w) \cdot m\bar{P},$$

where $\sum_{i=1}^m \alpha_i(w) \equiv \alpha(w)$. Micro and macro supplies must satisfy these functional relations if consistent aggregation is to be possible.

Suppose for the moment that micro supplies are indeed aggregable and then reveal that G has been chosen as Cobb-Douglas so that

$$(2) \quad Y = A\bar{P}^a w^{-a} = \alpha(w) + \beta(w)m\bar{P}.$$

This implies $Aw^{-a}\bar{P}^a = \beta(w)m\bar{P}$ and $\alpha(w) = 0$. A regression with this commonly used form must tend toward a unit elasticity supply curve as the aggregation errors tend toward zero. The aggregate supply elasticity must be unity! This conclusion can also serve as the basis for testing exact aggregation with mean price using the aggregate supply function. This latter equality also

requires that either $\alpha_i(w) = 0$ ($i = 1, \dots, m$) or that $\sum_{i=1}^m \alpha_i(w) = 0$ with some $\alpha_i \neq 0$. In the case that all $\alpha_i(w) = 0$, micro and macro supply elasticities are unity.

Now, consider the Laspeyres price index

$$P = \hat{P} = \frac{\sum_{i=1}^m p_i y_i}{\sum_{i=1}^m y_i}.$$

Again assume that $\sum_{i=1}^m y_i \equiv Y$. \hat{P} clearly is a function of Y and w . Because the denominator of \hat{P} is Y , it seems clear that the numerator depends on Y and w . Pope and Chambers have shown that the numerator (revenue) of \hat{P} is necessarily affine in Y . Thus, $\sum_{i=1}^m p_i y_i = -\alpha(w) + \beta(w)Y$ with $p_i y_i = -\alpha_i(w) + \beta(w)y_i$. Hence,

$$\hat{P} = \frac{-\alpha(w) + \beta(w)Y}{Y} \quad \text{and}$$

$$Y = \frac{\alpha(w)}{\beta(w) - \hat{P}}.$$

Only forms satisfying this last equation are candidates for $G(\hat{P}, w)$. For example, suppose as above that $G(\hat{P}, w)$ is Cobb-Douglas $A\hat{P}^a w^{-a}$. Comparing this with the above then requires $\beta(w) = 0$, $A = 1$, $a = -1$. Hence, a Cobb-Douglas can be used with the Laspeyres only if aggregate supply has a supply elasticity of minus one! Aggregate and micro revenues are constant. This condition forms the basis of a test for consistent aggregation with the Cobb-Douglas macro function and Laspeyres index. It also raises the possibility that the index and functional form may unwittingly tend to prescribe empirical work.

Single-Equation Price Aggregation-General Results

The previous examples are important special cases of a more general price aggregation problem: Find functions G , P , and H satisfying

$$(3) \quad G(P, w) = H(h_1(p_1, w), h_2(p_2, w), \dots, h_m(p_m, w)) \\ P = P(p_1, \dots, p_m; w).$$

Here p_i remains the price faced by the i th firm, and w is the vector of input and output prices which are common to all firms. The indexes ($i = 1, \dots, m$) delimit the number of firms

whose supplies or demands are aggregated. The functions h_i are the microeconomic response functions (e.g., supplies, demands, profits, or costs) to be aggregated. The function H represents the rule by which the aggregate quantity variable is constructed from these microeconomic response functions. For example, in both examples above, h_i is the supply of the i th firm and H is the summation operator. The function G is the aggregate behavioral function upon which analysis is based. In the examples above, G is the Cobb-Douglas industry supply function; P is the representative price used in the aggregate relationship. In the first example, P is the average price, while in the second it is the weighted average. Aggregation schemes which satisfy (3) are said to aggregate consistently.

Attention is restricted to strictly monotonic and differentiable H functions and G functions. This restriction represents only a slight loss in generality because virtually all commonly used functional forms satisfy these criteria. This assumption clarifies the intimate relationship between the aggregate price index and the microeconomic response functions.

Result 1. The aggregate price index P , consistent with (3), can always be expressed as a differentiable and monotonic function of the microeconomic response functions of the following form:

$$(4) \quad P = P^*(h_1(p_1, w), \dots, h_m(p_m, w); w).$$

P^* has partial derivatives

$$(5) \quad \frac{\partial P^*}{\partial h_i} = \left(\frac{\partial G}{\partial P} \right)^{-1} \left(\frac{\partial H}{\partial h_i} \right) \text{ and} \\ \frac{\partial P^*}{\partial w} \Big|_{h_i} = \left(\frac{\partial G}{\partial P} \right)^{-1} \left(\frac{\partial G}{\partial w} \right),$$

where the notation $\partial P^* / \partial w|_{h_i}$ denotes the partial derivative of P^* with respect to w holding the h_i functions constant.

Expressions (4) and (5) are direct consequences of the implicit function theorem (Courant, p. 117) applied to (3). The price-aggregation rule, P , inherits structural restrictions placed upon H . For example, suppose that the aggregate economic quantity is firmwise strongly separable in the microeconomic response functions. This includes the case where aggregate supplies, demands, shares, or profits are the sum of their micro counterparts. It also includes the case

where the log of the sum of the micro entities equals the log of the macro entity and so on. Functionally,

$$(6) \quad H(h_1, \dots, h_m) = \bar{H} \left(\sum_{i=1}^m g_i(h_i(p_i, w)) \right) \equiv \bar{H}(g).$$

Applying (4) to (6) gives the price aggregation rule consistent with (6),

$$(7) \quad P = \bar{P}^* \left(\sum_{i=1}^m g_i(h_i(p_i, w)); w \right) \equiv \bar{P}^*(g; w).$$

Expression (7) is firmwise strongly separable in the prices p_i . The reader can easily verify that expression (4) implies the following result (proved formally in Pope and Chambers):

Result 2. Let N be the set of integers $\{1, \dots, m\}$ and let $\Omega = (\Omega_1, \dots, \Omega_s, \dots, \Omega_s)$ be a mutually exclusive and exhaustive partition of N . Let Ω_p and Ω_h be the set of prices, p , and functions, h , partitioned according to the indexes in Ω . Then, for H , P , and h , monotonic and twice differentiable, with $H(h_1(p_1, w) \dots, h_n(p_n, w)) = G(P, w)$, P is strongly (weakly) separable in Ω if and only if H is strongly (weakly) separable in Ω .

Thus, one cannot divorce the structure of the price aggregate from the structure of the quantity aggregation rule. Once the researcher picks a price aggregate (quantity aggregation rule) the quantity aggregation rule (the price aggregate) cannot be chosen arbitrarily. Result 2 shows, for example, that choosing the price aggregate to be mean price (this rule is strongly separable) automatically rules out using quantity aggregation rules which are not strongly separable. Because most aggregation rules used in the construction of reported quantity aggregates are strongly separable aggregation rules, we consider further the practical implication of result 2.

Constructing Firmwise Strongly Separable Aggregates

To examine the implications of result 2, imagine that one chooses a price-aggregation rule

$$(8) \quad P = \bar{P} \left(\sum_{i=1}^m k_i(p_i, w); w \right) = \bar{P}(k; w)$$

which is firmwise strongly separable in the prices

p . [The average price is a special case of (8).] Result 2 now implies H must be also firmwise strongly separable in the h functions, i.e., it can be expressed as (6), to satisfy consistent aggregation. [Alternatively, by result 2, if one chooses a quantity aggregation rule satisfying (6), the price aggregation rule must satisfy (8).] Use this fact and differentiate both sides of (3) to determine in this case that

$$\frac{\partial G}{\partial p_i} = \frac{\partial G}{\partial P} \frac{\partial \bar{P}}{\partial k} \frac{\partial k_i}{\partial p_i} = \frac{\partial \bar{H}}{\partial g} \frac{\partial g_i}{\partial p_i} \quad i = 1, \dots, m.$$

Taking ratios gives, after a slight manipulation,

$$(9) \quad \frac{\partial k_i / \partial p_i}{\partial g_i / \partial p_i} = \frac{\partial k_j / \partial p_j}{\partial g_j / \partial p_j} \quad \text{for all } i \text{ and } j.$$

Expression (9) implies that these ratios must be the same for all i and j . By construction, each ratio can only depend upon the vector w and the price specific to the i th firm. Because they must be the same regardless of the firm considered (and thus the p_i), these ratios can only depend upon w —call this common ratio $\gamma(w)$. Integrating the differential equations implied by (9) gives

$$(10) \quad g_i(h_i(p_i, w)) = \gamma(w)k_i(p_i, w) + v_i(w) \quad i = 1, \dots, m$$

and

$$h_i(p_i, w) = g_i^{-1}[\gamma(w)k_i(p_i, w) + v_i(w)] \quad i = 1, \dots, m.$$

To aggregate consistently, the i th response function must be a monotonic transformation of an affine transformation of $k_i(p_i, w)$.

Limitations on Strongly Separable Aggregates

Table 1 presents a guide to constructing firmwise strongly separable price indexes and quantity indexes which are mutually consistent. The families of price indexes in the second column exhaust the possible alternatives consistent with the quantity indexes in the corresponding row of the first column. If the researcher chooses a price aggregate belonging to the second column of that table, the structure of the associated micro response functions is predetermined. Notice, in particular, that this relationship does not follow from any optimization hypothesis but from the arithmetic necessity of having both sides of aggregate equations consistent with one an-

other. Violating these principles in empirical work is, to use an old saw, "adding apples and oranges." Just as two apples and two oranges do not make four apples or four oranges, using inconsistent aggregation procedures violates the simple arithmetic laws upon which aggregation is purportedly based.

The limiting nature of these results can be seen clearly by considering using a geometric average of firm-level prices as a price index (row 5, column 2) to explain industry supply (the sum of firm supplies). From table 1, the firm-level supply functions consistent with aggregation must belong to the family of functions,

$$\alpha_i(w) + \hat{\beta}(w)\theta_i(w)\ln p_i \quad i = 1, \dots, m.$$

Why Quantity (Price) Aggregates Inherit the Structure of Price (Quantity) Aggregates

When either the price or the quantity index is specified to be firmwise strongly separable, its counterpart in the aggregation scheme inherits both this structural property as well as the general functional structure imposed. Why is this result obtained? The key lies in recognizing that the three level sets associated with the aggregate response function (G), the aggregate price index (P), and the aggregate quantity index (H), respectively

$$\{p: G(P(p_1, \dots, p_m); w) = G\}$$

$$\{p: P(p_1, \dots, p_m; w) = P\}$$

$$\{p: H(h_1(p_1, w), \dots, h_m(p_m, w)) = H\}$$

have the same graph in p -space for fixed w . Thus, once one specifies the curvature properties of, say, the price aggregation rule in p -space, one also specifies the curvature of the level set of the quantity aggregation rule and the aggregate response function. Put another way, each of these functions when considered as functions of the prices over which one is aggregating are monotonic transformations of the others (see result 1). Hence, once one of these functions is specified (say H), the whole family of possible functions available for the two other functions (G and P) is known. Because these latter families correspond to monotonic transformations of the original aggregation rule specified (there is an infinity of such possible transformations), there is an infinity of possible rules which are consistent with aggregation over prices. This is reflected

Table 1. The Structure of Price Aggregators and Aggregation Functions

Aggregate Function (<i>H</i>)	Class of Price Aggregators <i>P</i>
General structure	
$H\left(\sum_{i=1}^m h_i(p_i, w)\right)$	$P^*\left(\sum_{i=1}^m (\alpha_i(w) + \beta(w)h_i(p_i, w)); w\right)$
$H\left(\sum_{i=1}^m \hat{\alpha}_i(w) + \hat{\beta}(w)k_i(p_i, w)\right)$	$P^*\left(\sum_{i=1}^m k_i(p_i, w); w\right)$
Specific examples	
$\sum_{i=1}^m A_i p_i^\alpha w^{1-\alpha}$	$P^*\left(\sum_{i=1}^m \alpha_i(w) + \beta(w)A_i p_i^\alpha w^{1-\alpha}; w\right)$
$H\left(\sum_{i=1}^m \hat{\alpha}_i(w) + \frac{\hat{\beta}(w)}{m} p_i\right)$	$\frac{1}{m} \sum_{i=1}^m p_i$
$H\left(\sum_{i=1}^m \hat{\alpha}_i(w) + \hat{\beta}(w)\theta_i(w) \ln p_i\right)$	$\prod_{i=1}^m p_i^{\theta_i(w)} = \exp\left[\sum_{i=1}^m \theta_i(w) \ln p_i\right]$
$\sum_{i=1}^m (a_i p_i^{\alpha_i} + b_i w^{\alpha_i})^{1/\alpha_i}$	$P^*\left(\sum_{i=1}^m \alpha_i(w) + \beta(w)(a_i p_i^{\alpha_i} + b_i w^{\alpha_i})^{1/\alpha_i}; w\right)$
$H\left(\sum_{i=1}^m \hat{\alpha}_i(w) + \hat{\beta}(w)c_i p_i^{\alpha(w)}\right)$	$\left(\sum_{i=1}^m c_i p_i^{\alpha(w)}\right)^{1/\alpha(w)}$

in table 1, for example, by the fact that the average price equation will aggregate firm-level supplies of the general form for any possible *H* function that is monotonic in its argument.

However, once a specific *H* function is chosen, say the sum, then choice of a specific price aggregator places direct restrictions on the form of the functions to be aggregated. Only special classes of *h*() functions can then be consistent with both *H*, *P*, and the requirement that the latter be expressible as a monotonic transformation of the former. This is why, once exact forms of *P* and *H* are specified, we can infer exactly the type of supply or demand functions (if any exist) that are consistent with these aggregators. For example, the Laspeyres price index is not generally firmwise strongly separable. But $H = \sum_{i=1}^m h_i$ is firmwise strongly separable. Thus, if this *H* is to be used with a Laspeyres index, only firm-level supply functions which make the Laspeyres index firmwise strongly separable in the *p_i*'s are consistently aggregable. Pope and Chambers demonstrate that these functions all belong to the family

$$h_i(p_i, w) = \frac{\alpha_i(w)}{\beta(w) - p_i}.$$

Therefore, consistent aggregation using the Laspeyres index requires that supplies be of this microform. If this form is rejected by the data, so also is consistent aggregation using the index.

These ideas are portrayed geometrically in figure 1. The level curves for *G*, *P*, and *H* are represented by the curve (set) *a*–*b*. The marginal rate of substitution of the curve is $(\partial P / \partial p_j) / (\partial P / \partial p_i)$ or equivalently $(\partial h_j / \partial p_j) / (\partial h_i / \partial p_i)$ which is nonnegative. In general the marginal rate of substitution may rise or fall with increasing *p_i*. For strongly separable aggregation rules,

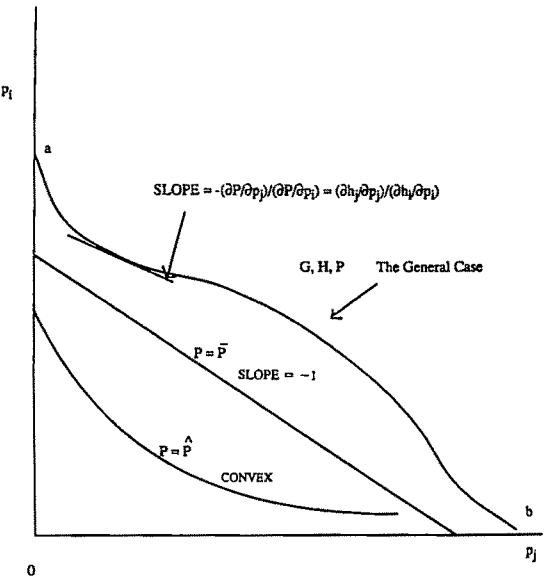

Figure 1. Level curves and aggregation

the marginal rate of substitution is unaffected by variations in p_k ($k \neq i, j$). When P equals average price, \bar{P} , the marginal rate of substitution is constant at unity. In the Laspeyres case, \bar{P} , the slope is nonconstant and equal to $\alpha_j(w)(\beta(w) - p_j)^{-2}/\alpha_i(w)(\beta(w) - p_i)^{-2}$. The marginal rate of substitution is diminishing, and hence aggregate price increases with a mean-preserving spread in the distribution of prices. Contrasting \bar{P} and P we see that mean-preserving changes in the p -distribution must have no effect on the aggregates if \bar{P} is used, but mean-preserving spreads in the p -distribution evoke aggregate change if P is used.

Finally, exact knowledge of P , H , and the h functions lets one infer $G(P, w)$ because differentiating (3) gives

$$(11) \quad \frac{\partial G}{\partial P} \frac{\partial P}{\partial p_i} = \frac{\partial H}{\partial h_i} \frac{\partial h_i}{\partial p_i}.$$

If $\partial P/\partial p_i$ and $\partial H/\partial h_i$ $\partial h_i/\partial p_i$ are known, (11) can be solved for $\partial G/\partial P$, which can, in principle, be integrated to obtain G .

A simple example illustrates: Suppose that $H = \sum_{i=1}^m h_i$ and P is an average price. By table 1, the h functions are of the general form

$$h_i(p_i, w) = \alpha_i(w) + \frac{\hat{\beta}(w)}{m} p_i \quad i = 1, \dots, m.$$

Differentiating the resulting (11) with respect to p_j for ($j \neq i$) implies

$$\frac{\partial^2 G}{\partial P^2} = 0,$$

or that the aggregate response function must be linear in the aggregate price. As long as H is linear G always inherits the same form as the h_i functions. As another example, we have already shown above for the Laspeyres price index and H linear that

$$G(P, w) = \frac{\alpha(w)}{\beta(w) - P},$$

which is to be compared with the associated h_i 's shown above.

Testing Aggregation Restrictions

As indicated above, choice of a supply aggregation rule and a price aggregator conjointly imply that micro supply equations are restricted to certain families of functional forms. For ex-

ample, table 1 suggests that, if aggregate supply equals the sum of firm supplies while the aggregate price represents the average price across firms, then firm-level supply equations must assume the Gorman polar form:

$$z_i(p_i, w) = \theta_i(w) + \beta(w)p_i.$$

So one way to test whether the sum of firm supplies and the average price aggregate consistently is to test whether the Gorman polar form accurately portrays the variation of the microeconomic price and supplies. The Gorman polar form is a special case of the general quadratic function,

$$y_i(p, w) = \theta_i(w) + \beta_i(w)p_i + \gamma_i(w)p_i^2.$$

Because the quadratic function provides a second-order flexible approximation of any differentiable $y_i(p, w)$, it has proved a popular representation (Shumway) especially when one is interested in testing for the linear special case. (The popular translog function, having the Cobb-Douglas as the linear special case, can also be interpreted as a quadratic function.) Using this approach, a statistical test for the validity of the linear aggregation hypothesis could be tested within the framework of a second-order flexible maintained model by testing the restrictions statistically,

$$\beta_i(w) = \beta(w) \quad i = 1, \dots, m$$

$$\gamma_i(w) = 0 \quad i = 1, \dots, m,$$

against the more general quadratic model.

Our general procedure for testing aggregation restrictions follows a similar approach: once a specific form is deduced as being required by the choice of the aggregate quantity and the aggregate price, nest that form within a more general form which is at least second-order flexible in prices, and then test the specific model against the more general form. To illustrate the procedure, we consider the conditions required to permit aggregation of wheat supplies and wheat prices across states using the aggregation rule that USDA uses to calculate its season average price for wheat as reported in *Agricultural Statistics*. The season average price reported in that publication is given by

$$P = \frac{\sum_{i=1}^{50} p_i y_i}{\sum_{i=1}^{50} y_i},$$

where y_i is now wheat supply in state i and

p_i is the estimated average price of wheat in state i .

A number of supply aggregates could be chosen to be combined with P , but one that is particularly attractive is the implicit supply aggregate (Y) defined by Fisher's product test:

$$Y \cdot P = \sum_{i=1}^{50} p_i y_i.$$

Of course, this quantity aggregate is just the sum of state supplies so that

$$Y = \sum_{i=1}^{50} y_i.$$

As noted above, Pope and Chambers have shown that the only family of supply functions consistent with this form is

$$y_i = \frac{\alpha_i}{\beta - p_i} \quad (i = 1, \dots, m).$$

To apply our procedure, we first rewrite this equation in the equivalent implicit form

$$(12) \quad y_i(\beta - p_i) = \alpha_i \quad (i = 1, \dots, m).$$

Because it has only two parameters, this equation is at most first-order flexible in prices. However, in a manner analogous to the discussion of the Gorman polar form, we note this form is a special case of the second-order flexible form:

$$(13) \quad y_i(\beta_i - p_i) + \gamma_i \cdot (\beta_i - p_i)^2 = \alpha_i \quad i = (1, \dots, m).$$

Because this form has three parameters (α_i , γ_i , β_i), it is potentially second-order differential flexible.

Within this maintained model, a test for the aggregation restrictions then becomes a test of the linear parametric restrictions,

$$(14) \quad \begin{aligned} \beta_i &= \beta \quad i = 1, \dots, m \\ \gamma_i &= 0 \quad i = 1, \dots, m. \end{aligned}$$

To execute this test, we employed a data set consisting of observations on wheat supply and wheat price for one state from each of the four main production regions in the United States for the period 1958–87. The states were Washington, Oklahoma, South Dakota, and Pennsylvania. We proceeded as follows: first, we fit the general form of the implicit supply equation to the data; second, we tested whether the form

$$(15) \quad y_i(\beta_i - p_i) = \alpha_i,$$

i.e., $\gamma_i = 0$, represented an acceptable explanation

of the price and quantity covariation in the model; and we then tested whether within this latter model the aggregable form (12) represented an acceptable restriction of the data. A direct test of the acceptability of this last version of the model against the most general version was also conducted.

The statistical model appended an additive error to the implicit supply equation represented above. The error term was assumed to have mean zero and be intertemporally independently distributed but with contemporaneous correlation across states. The estimation procedure was systems maximum likelihood and the results are reported in table 2. We first determine whether the aggregation restrictions represent a reasonable depiction of the sample data. When these seven restrictions are imposed upon the model ($\beta_i = \beta$, $\gamma_i = 0$ for all i), the log of the likelihood function decreased from -529.5148 to -553.1016 . Using an asymptotic chi-square test would lead to the rejection of the null hypothesis of the aggregation restrictions at all reasonable levels of confidence.

It is interesting to note, however, that the failure to accept the aggregation restrictions appears to emerge from the fact that the form

$$y_i(\beta_i - p_i) = \alpha_i$$

is a statistically inferior representation of the covariation in the data than the more general quadratic form. When this latter model is treated as the maintained model, one cannot reject the null hypothesis that $\beta = \beta_i (i = 1, \dots, m)$.

These statistical results suggest that

$$\begin{aligned} Y &= \sum_{i=1}^m y_i \text{ and} \\ P &= \frac{\sum_{i=1}^m y_i p_i}{\sum_{i=1}^m y_i} \end{aligned}$$

represent unacceptable supply aggregates for the current data. However, it is now possible to use the results contained in table 1 to construct alternative aggregates which are more consistent with the data. Suppose, for example, that we decide to retain $Y = \sum_i y_i$ as the supply aggregate. Table 1 and the results reported in table 2 then indicate that the aggregate price must belong to the general family

$$P = P^* \left(\sum_{i=1}^m \tau_i + \delta \left(\frac{\alpha_i}{\beta_i - p_i} - \gamma_i(\beta_i - p_i) \right); w \right).$$

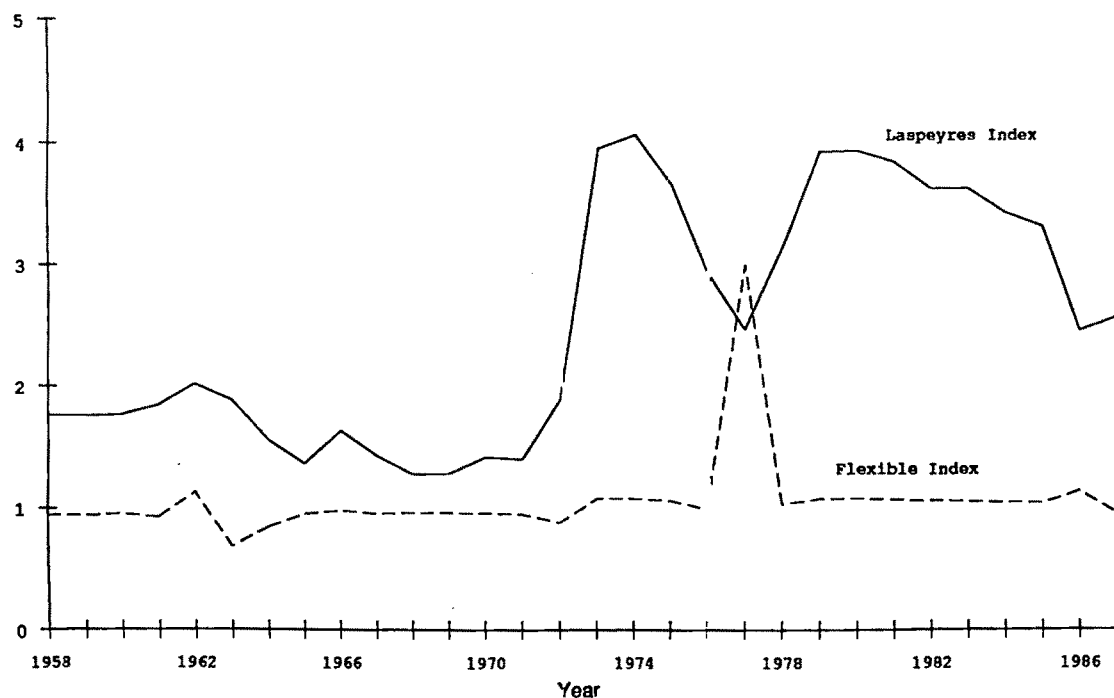

Table 2. Laspeyres Aggregation of Washington, Oklahoma, South Dakota, and Pennsylvania Wheat Production

Parameter	Unconstrained Estimates ^a	Constrained Estimates ^b	Constrained Estimates ^c
α_w	25.38 (28.51)	16.10 (29.53)	-32.89 (24.83)
α_o	-32.55 (26.41)	30.08 (33.48)	-26.86 (27.61)
α_s	7.95 (14.14)	4.59 (12.17)	-5.44 (10.82)
α_p	-4.74 (1.86)	-8.98 (2.60)	2.50 (2.21)
γ_w	30.85 (6.39)		
γ_o	59.45 (9.46)		
γ_s	10.23 (5.07)		
γ_p	1.72 (0.34)		
β_w	2.66 (0.13)	2.91 (0.19)	2.46 (0.09)
β_o	1.93 (0.16)	2.89 (0.19)	2.46 (0.09)
β_s	2.53 (0.14)	2.65 (0.14)	2.46 (0.09)
β_p	1.58 (0.12)	1.45 (0.19)	2.46 (0.09)
Log likelihood	-529.51	-542.48	-553.10

^a These are estimates of (13), where subscripts denote Washington, Oklahoma, South Dakota, and Pennsylvania, respectively. Standard errors are reported below each coefficient.

^b Constrained estimates are estimates of (15).

^c Estimates of (12); that is, all of the restrictions in (14) are imposed on (13).

**Figure 2. Two wheat price indexes**

For the sake of concreteness, take $\tau_i = 0$ ($i = 1, \dots, m$), $\delta = 1$, and P^* to be the exponential function. Figure 2 presents a graphical depiction of this aggregate price for the four sample states and compares it with the similarly computed Laspeyres index.

The preceding test has supposed that micro-economic data were available to test the aggregation hypothesis. Unfortunately, the empirical reality is that researchers frequently have only aggregate data with which to work. If that is the case, then the aggregation restrictions must be tested at the aggregate level. In an earlier section, we have shown that if the above price and quantity aggregates are used, then the aggregate supply relation must assume the same general form as the micro supply equations, i.e.,

$$Y = \frac{\alpha(w)}{\beta - \hat{P}}.$$

Therefore, a test for the aggregation restriction using aggregate data can be constructed along similar lines to those above, i.e., test this form (in implicit form) against the more general form,

$$(16) \quad Y(\beta - \hat{P}) + \gamma \cdot (\beta - \hat{P})^2 = \alpha(w).$$

Estimated versions of the aggregate model are presented in table 3. Estimates were obtained by the same procedure used for the micro forms. The aggregation restriction is that $\gamma = 0$. Because we now proceed as if no data are available on supply-price covariation at the microeconomic level, the aggregation test reduces to testing for the validity of the aggregate form versus (16). But because the asymptotic t -statistic on the estimate of γ exceeds 5, the hypothesis of aggregability is rejected at this level as well. Both macro and micro tests result in the same conclusion. The data are inconsistent with aggregation using the Laspeyres form.

Table 3. Laspeyres Aggregation—The Aggregate Equation

Parameter	Unconstrained Estimates ^a	Constrained Estimates ^b
α	-117.20 (56.44) 126.74	949.41 (181.56)
γ	(22.91) 1.15	5.74
β	(0.34)	(0.57)
Log likelihood	-181.32	-203.75

^a This column contains estimates of (16).

^b Column 3 contains estimates of (16) with γ constrained at zero.

Although this data set has led to the rejection of the Laspeyres aggregation hypothesis, it is clear that an acceptance of the aggregation hypothesis using aggregate data would have enabled us to identify a representation of the micro supplies consistent with the aggregate data. By the above, if aggregation had been accepted, then

$$\sum_{i=1}^m p_i y_i = -\alpha(w) + \beta(w) \sum_{i=1}^m y_i,$$

so that one representation of each $y_i(p_i, w)$ consistent with the data would be

$$y_i(p_i, w) = \frac{\alpha(w)/m}{\beta(w) - p_i}.$$

Conclusion

Aggregation across commodity groups has received considerable attention in agricultural economics. Such attention has focused in large part on testing for separable commodity groups in input, output, or price space and attempting to discover the nature of the aggregate index.

Similar in spirit (but not form) is the analysis of aggregate price indexes where aggregation is across economic entities. Because this form of aggregation is widespread, the practical implications of methods for more accurate measurement are large.

We have considered the implications of aggregation on aggregate response and the form of aggregate indexes. We have shown that exact aggregation imposes a definite structure on supplies, demands, or profits. In particular, commonly used price indexes imply specific families of responses with direct implications for elasticity measurement. These implications can be used to construct tests for exact aggregation.

By way of an empirical inquiry on wheat supply, the most commonly used and reported index of aggregate price was not supported by exact aggregation. Based upon these findings, we proposed, calculated, and reported one of many possible empirically based indexes which are consistent with the supply-price covariation in the data. The testing procedures presented here can be used directly to aid in the discovery of simple but empirically relevant aggregates for all agricultural price series.

On Nonlinear Dynamics: The Case of the Pork Cycle

Jean-Paul Chavas and Matthew T. Holt

New methods for analyzing nonlinear dynamic processes are used to evaluate the hog-corn price ratio. The results present evidence of nonlinear dynamics in the pork cycle. Moreover, while GARCH processes account for some of the nonlinearities, the pork cycle is apparently characterized by more complex dynamic forms. The empirical analysis provides some evidence of the presence of chaos in the pork cycle. The results also indicate that the dynamic process generating the pork cycle is nonlinear and cannot be adequately characterized by a small number of state variables.

Key words: business cycle, chaos, GARCH, nonlinear dynamics.

The pork market has been viewed by economists as a clear example of a business cycle. Beginning with Coase and Fowler, an extensive body of research has focused on identifying the source and nature of the pork cycle (e.g., Breimyer, Larson, Jelavich, Jameson). For example, Harlow proposed to explain a four-year hog cycle in the context of the cobweb theorem and a delayed supply response to market price. Using harmonic analysis, Talpaz argued that hog prices follow several different cycles, each with a different period and magnitude. Using linear time-series models, Wallis, Shonkwiler and Spreen, Bessler and Kling, and Kaylen presented empirical evidence on the existence and nature of the pork cycle. Although the results often vary according to the period analyzed and/or the methodology used, the existence of a pork cycle has been strongly supported by the empirical evidence.

In many respects, the continuing presence of any price cycle is disturbing for economists. If a predictable price cycle exists, then producers responding in a countercyclical fashion could earn larger than "normal" profits over time (Hayes and Schmitz). Such profits could occur even with lags in the production process because predictable price movements would still influence pro-

duction decisions. Eventually, countercyclical production response would smooth out price fluctuations at the market level, causing the cycle to disappear.

The implication is that predictable price cycles are incompatible with rational producer behavior. Hence, the continuance of a business cycle could imply that producers are not behaving rationally and are ignoring important information. The assumption of naive producer behavior, while dating back to Ezekiel and others, still is a basic premise in much of the literature on livestock supply response.

An alternative explanation for the existence of a business cycle is that the cycle itself is not perfectly predictable. The law of motion underlying the business cycle may be a deterministic nonlinear relationship that generates unpredictable patterns (e.g., Grandmont and Malgrange). In recent years, examples of nonlinear, deterministic dynamic systems that produce seemingly random behavior have been reported in both the physical and social sciences (May, Grandmont and Malgrange). Such systems, usually called "chaotic," are necessarily associated with nonlinear dynamics (Hao, Baumol and Benhabib).

Until recently, economists have not considered that unpredictable patterns could result from deterministic, nonlinear dynamics. Recent work by Day; Brock; Scheinkman and LeBaron; Brock and Sayers; Frank, Genzay, and Stengos and others has, however, begun to examine the prospect that observed economic events could result from deterministic chaos. This research

Jean-Paul Chavas and Matthew T. Holt are a professor and an assistant professor, Department of Agricultural Economics, University of Wisconsin.

Financial support was provided by a Hatch grant from the College of Agriculture and Life Sciences, University of Wisconsin.

The authors would like to thank two anonymous reviewers for helpful comments on an earlier draft of this paper.

has resulted in a set of tools and statistical tests useful for investigating deterministic nonlinear dynamics in economic analysis.

The objective of this paper is to consider whether a particular business cycle, the pork cycle, may be characterized by a deterministic nonlinear dynamic process, and hence may not be fully predictable. In so doing, we present some of the analytical tools currently available for nonlinear dynamic analysis and illustrate their application to the pork cycle. In the next section deterministic nonlinear dynamic systems are briefly reviewed. Methods for detecting nonlinear dynamics in economic data are discussed; and the dynamics of the hog-corn price ratio in the United States is investigated.

Nonlinear Dynamics

The focal point of most dynamic analysis is a system of difference equations which dictate how a vector of state variables, y_t , evolves over time, t .¹ In general form, a system of n first-order difference equations can be written as

$$(1) \quad y_{t+1} = f(y_t),$$

where y_t is an n -vector of state variables and the function f consists of n separate linear or nonlinear component functions. The system of first-order difference equations in (1) provides a basis for analyzing any discrete-time dynamic system; any system of second- or higher-order difference equations can always be reformulated as an equivalent first-order system (Luenberger, p. 96).

Linear State Equations

The properties of the state equations (1) are best understood in the context of linear models where $f(y_t) = Ay_t$, and A is an $(n \times n)$ matrix. In this situation, an analytical solution to the time path of the state variables can be obtained (Chow). It is well known that linear models result in state trajectories that can exhibit several types of behavior: trajectories that converge to a steady state, trajectories that become arbitrarily large over time, or periodic trajectories that oscillate or cycle.

For linear systems, the type of behavior can be deduced from the characteristic roots of the system matrix, A . Complex roots imply oscillations and cyclical patterns (e.g., Luenberger, p. 158). The system will also be stable (unstable) whenever the modulus of the dominant characteristic root is less than (greater than) one.

Because linear models exhibit well-known analytical properties and are empirically tractable, they have been used extensively to investigate dynamic behavior in economics. Indeed, time-series analysis and the analysis of distributed lags in econometrics have mostly used linear models. Also, most studies of pork market dynamics have used linear models (e.g., Wallis, Shonkwiler and Spreen, Bessler and Kling, Kaylen).

Linear models can provide useful insights into the dynamic properties of economic systems. But, are economic models always best characterized with linear state equations? Many economists would agree that dynamic relationships in economics are often fundamentally nonlinear, but that linear systems provide a useful "first-order" approximation to the true (but unknown) laws of motion. This argument is consistent with the methods frequently used to analyze the stability of nonlinear systems. That is, according to Lyapunov's first method, any system of nonlinear differentiable state equations can be linearized at a point (Luenberger, p. 324). The analytical results for inferring "global" stability in linear systems can then be used to infer "local" stability in nonlinear systems.² Several implications of using linear systems to approximate nonlinear systems are discussed below.

Nonlinear State Equations

By comparison, relatively little research has focused on nonlinear dynamics in economics. Unlike linear models, tractable methods for solving and analyzing nonlinear systems are not generally available. When analyzing nonlinear models, it is often necessary to obtain results numerically. Consequently, recent progress in computer technology has created new opportunities for investigating the dynamic properties of nonlinear state equations.

Quantitative predictions can differ between

¹ The discussion is limited to discrete-time dynamic systems. Similar results could be obtained for continuous-time systems. In this case, the dynamic equations (1) would take the form of first-order differential equations instead of difference equations.

² The term local is used when evaluating the stability of nonlinear systems because the results hold only in some neighborhood of the point of approximation.

systems of linear and nonlinear state equations. "Approximation errors" are introduced if a linearized model is used to represent a nonlinear system. Such considerations arise in policy analysis or in forecasting when dynamic simulations are used to predict values for the state variables that are well beyond the observed range of the data.

Moreover, nonlinear state equations can exhibit dynamic behavior that is qualitatively different from that of linear state equations. Nonlinear state equations can exhibit dynamic patterns that cannot, under any circumstances, be generated or reproduced by a system of linear state equations. These new and different patterns have been grouped in the literature under the general term "chaos."

In the early 1960s, Lorenz first identified chaotic patterns in the context of a dynamic weather model. He discovered that a deterministic system of three differential equations could generate nonperiodic but bounded solutions. In 1975, Li and Yorke introduced the term "chaos" to denote the apparently random output of certain nonlinear dynamic systems. In 1976, May cited the complicated dynamics generated by simple population models. Over the last fifteen years, there has been growing interest across disciplines (e.g., physics, climatology, ecology, economics) in nonlinear deterministic models and the highly irregular trajectories they can generate.

The word "chaos" refers to "unpredictability" in completely deterministic dynamic systems. The concept is at odds with the more traditional view that accurate predictions are always possible from a deterministic model. Chaos means, for example, that apparently random fluctuations in some state variables are not necessarily associated with a stochastic process or with errors in measuring the model's parameters (e.g., Brock). The potential for chaos warns us of the dangers of extrapolation and of the difficulties of economic forecasting. It also suggests a need for a careful reevaluation of the traditional way of thinking about stochasticity in modeling. Finally, chaos should not be equated with disorder. Rather, chaos is considered a kind of order without periodicity.

Unfortunately, few analytical results are available for characterizing the potential for, and nature of, chaos associated with a general system of state equations as in (1). Most analytical results have been obtained using particular specifications of (1) (e.g., Hao). Apparently, nonlinearities can appear in so many ways that it is

difficult to develop a general criterion or classification scheme for characterizing chaos. Nonetheless, chaos occurs in a variety of nonlinear dynamic models that are often relevant in explaining a fairly wide class of observable events (Hao).

Deterministic Chaos, an Example

The above discussion suggests that chaos is best illustrated in the context of specific models. One useful example is given by the deterministic state equation

$$(2) \quad y_{t+1} = \alpha y_t(1 - y_t),$$

where y_t is a scalar and α is a positive "tuning" parameter. Equation (2) is the logistic difference equation discussed by May. It is one of the simplest nonlinear state equations possible: it is a first-order quadratic difference equation with a single state variable. However, as shown by May, this simple deterministic state equation can generate complex dynamics. The time path of y_t in (2) is determined completely by the parameter α and by the initial condition, y_0 . The logistic equation (2) is unstable for any $y_0 < 0$ or $y_0 > 1$. We focus on the case where $0 < y_t < 1$ and $0 < \alpha < 4$. In these intervals, the dynamic properties of (2) depend entirely on the value of the tuning parameter, α .

For $0 < \alpha < 3$, model (2) is stable and converges to a unique steady state for any initial condition y_0 , $0 < y_0 < 1$. For $3 < \alpha < 3.5699$, the logistic equation exhibits cyclical patterns. For any initial condition, $0 < y_0 < 1$, the state variable converges on stable cycles of period 2^n , where n is an integer that depends on α . For example, if $3 < \alpha < 3.4495$, then $n = 1$ and the model would exhibit a two-period cycle. As α increases from 3.4495 to 3.5699, n takes on successively the values of 2, 3, 4, ..., each value corresponding to a stable cycle of period 4, 8, 16, ... (see May). In other words, as α increases from 3 to 3.5699, first there is one stable two-period cycle; then a four-period cycle emerges; then an eight-period cycle appears, and so on, ad infinitum. Given $0 < \alpha < 3.5699$, model (2), therefore, exhibits either stable or cyclical patterns in the interval $0 < y_t < 1$. That is, the state variable y_t would eventually converge to its "attractor": the point or set of points (e.g., limit cycle) describing the stable equilibrium of the system. Such predictable patterns can be found in linear models and are not specific to nonlinear models.

The dynamic properties of (2) are of particular interest, however, when $3.5699 < \alpha < 4$. In this region, model (2) exhibits "chaotic" behavior. Chaos implies that "small" changes in the initial condition, y_0 , can give rise to time paths that eventually diverge. Such divergence has been called "sensitive dependence to initial conditions" and is illustrated numerically by Baumol and Benhabib (pp. 93–95) for the logistic equation (2). Sensitivity to initial conditions shows that long-term predictions from a chaotic system are virtually impossible. This is the point first made by Lorenz, who argued that weather patterns are deterministic but chaotic, implying the impossibility of accurate long-term weather predictions.³

The divergence of neighboring paths does not preclude the convergence of the state variables to a bounded set of points. This bounded set of points is called a "chaotic attractor." More specifically, a chaotic attractor is an uncountable set of points attracting all paths starting within the neighborhood of the set, where such paths are aperiodic. Aperiodicity here means the existence of an infinite number of different periodic cycles that never repeat themselves. Thus, under chaos, an uncountable number of initial points y_0 gives totally aperiodic (although bounded) trajectories.

One implication of nonlinear dynamics is that a chaotic deterministic system can generate a time series that appears completely random. This, in turn, raises the issue of distinguishing between a random process and a chaotic deterministic process.⁴ For example, standard statistical tests relying on the spectrum or on the autocovariance function may suggest that a chaotic trajectory is indistinguishable from a trajectory generated by a "white noise" stochastic process (Brock and Sayers). In this case, standard tests for "randomness" could not discriminate between a stochastic explanation and a deterministically chaotic explanation of a time series. This indicates an important weakness of the traditional linear statistical approach to time-series

analysis. It also suggests a need for different methods in the analysis of nonlinear dynamic processes.

Tools for Nonlinear Dynamic Analysis

Nonlinear dynamic analysis is fairly new; it has received serious attention in the scientific community only during the last fifteen years. Consequently, the analytical tools for investigating nonlinear dynamic systems are still being developed. In this section, we briefly review some of the tools currently available and discuss their potential for empirical analysis.

Consider a univariate time-series of length T , represented by the scalar x_t . We wish to investigate the nonlinear dynamics of x_t , where

$$(3a) \quad x_t = h(y_t),$$

$$(3b) \quad y_{t+1} = f(y_t), \quad t = 1, 2, \dots, T.$$

Here, (3a) is the observer equation, (3b) is the equation of motion, and y_t is an $(n \times 1)$ vector of state variables characterizing the dynamics of x_t . Assume that the x_t 's are observed but the state variables y_t are not. The problem then is how to use observations on the x_t 's to investigate the underlying dynamic structure of the state variables. We assume that the functions $h(\cdot)$ and $f(\cdot)$ in (3) are differentiable and that the process $y_{t+1} = f(y_t)$ possesses a unique attractor. Three questions related to the equation of motion (3b) are of interest: (a) how can one tell whether the dynamic properties of x_t are chaotic? (b) how can one uncover the dimension, n , of the state vector y_t that underlies the dynamic properties of x_t ? And (c) how can one test for the existence of nonlinearities? Each issue is addressed in turn.

Identifying Chaos

Chaos is associated with the local divergence of neighboring paths in the attractor. Given this local property, consider the linearized version of model (1) around some resting point, \bar{y} :

$$y_{t+1} = \bar{y} - A(\bar{y})\bar{y} + A(\bar{y})y_t,$$

where $A(\bar{y}) = \partial f / \partial y(\bar{y})$. In principle, the modulus of the characteristic roots of $A(\bar{y})$ could be averaged over a trajectory to obtain a set of global measures.⁵ Such measures are called "Lyapu-

³ Using his simple three-equation nonlinear deterministic model, Lorenz discovered that long-term simulations were extremely sensitive to the initial conditions, thus implying the unpredictability of long-term weather patterns.

⁴ To the extent that random variables are used to represent part of the real world we do not understand well, the issue may not be to choose between a random versus a deterministic explanation of observable phenomena. Rather, the motivation should be to obtain better explanations for the seemingly "unpredictable" events that often occur in the real world. Chaotic models may help improve understanding of certain phenomena beyond that which is possible for stochastic models.

⁵ The characteristic roots of $A(\bar{y})$ determine the local stability of the state equation (1). The system is locally stable (unstable) if the modulus of the dominant root of $A(\bar{y})$ is less than (greater than) one.

nov exponents": they are generalizations of the modulus of characteristic roots along general forward trajectories. In the case of a single state system, $n = 1$, $A(\bar{y})$ is a scalar, and there is only one Lyapunov exponent defined as

$$\lambda = \lim_{T \rightarrow \infty} \frac{1}{T} \sum_{i=1}^T \ln(|A(y_i)|).$$

From the above discussion, $\lambda > 0$ corresponds to chaotic trajectories ($|A(\cdot)| > 1$ identifying local divergence) while $\lambda < 0$ corresponds to nonchaotic trajectories ($|A(\cdot)| < 1$ identifying local stability). In the general case of n state variables, there exist n Lyapunov exponents, $\lambda_1, \lambda_2, \dots, \lambda_n$.⁶ Supposing that $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$, then λ_1 denotes the largest Lyapunov exponent. For inferring chaos, it follows then that a positive largest exponent, $\lambda_1 > 0$, corresponds to chaotic trajectories, while $\lambda_1 < 0$ corresponds to nonchaotic trajectories. Thus, an empirical estimate of the largest Lyapunov exponent λ_1 will provide a measure of the existence of chaos in dynamic analysis.

Wolf et al. proposed a numerical algorithm for calculating the Lyapunov exponents of a time series. While the statistical properties of their estimator are not yet known, the Wolf et al. es-

is given in part by Takens' theorem, which states that the dynamics of m -histories x_t^m is equivalent to the dynamics of y over its attractor when $m \geq 2n + 1$ (Takens). This indicates that the smallest unit useful for dynamic analysis is given by x_t^m in (4) with $m \geq 2n + 1$.

Second, if the unobserved state equation (1) is identifiable, one way to measure the "dimension" of the attractor of y_t is to use the generalized definition of dimension proposed by Hausdorff. (See Grassberger and Procaccia for details.) In general, the Hausdorff dimension D of the attractor of y_t is at most equal to n , the dimension of the state vector y_t . However, the Hausdorff dimension D of a chaotic attractor could be a non-integer and smaller than n . An often cited example of a non-integer dimension (also called fractal dimension) is the Cantor set which has dimension $D = .6309$.⁷

Although the Hausdorff dimension D has received much attention in the literature, it is difficult to compute empirically. Consequently, Grassberger and Procaccia (GP) proposed the "GP correlation dimension" α as an alternative measure

$$(5) \quad \alpha = \lim_{\epsilon \rightarrow 0} \ln(C_m(\epsilon)) / \ln(\epsilon),$$

where

$$(6) \quad C_m(\epsilon) = \lim_{T \rightarrow \infty} \{\text{number of pairs } (i, j) \text{ whose distance, } \|x_i^m - x_j^m\|, \text{ is less than } \epsilon, i \neq j\} / (T^2 - T).$$

timator of λ_1 does provide a basis for detecting the presence of chaos in a given time series.

The Dimension of the Attractor

Noting from (3) that $y_{t+2} = f(f(y_t)) = f^2(y_t)$ and $y_{t+k} = f(f^{k-1}(y_t)) = f^k(y_t)$, $k = 1, 2, \dots$, consider the m -history

$$(4) \quad \begin{aligned} x_t^m &= (x_t, x_{t+1}, \dots, x_{t+m-1}) \\ &= (h(y_t), h(f(y_t)), \dots, h(f^{m-1}(y_t))) \\ &= J_m(y_t), \end{aligned}$$

where $J_m(y_t)$ is a mapping from R^n to R^m . Because x_t is observed but y_t is not, the first question addresses the minimum number of observations on x_t that are needed to recover the unobserved state equations in (3). The answer

Grassberger and Procaccia show that the GP correlation dimension α is a lower bound estimate of the Hausdorff dimension, where $\alpha \leq D$. They also argue that, in most cases, $\alpha \cong D$, implying that α can provide a useful measure of the underlying structure of the attractor of y_t . The empirical estimation of the GP correlation dimension is also computationally convenient and has several nice properties (Brock). Even though the statistical properties of this estimator are unknown at this time, the GP measure α is a useful method for identifying the minimum number of state variables needed in the dynamic analysis of a time series.

⁶ See Benettin, Galgani, and Strelcyn for a general definition of Lyapunov exponents and for a proof of their existence.

⁷ To see this, consider a Cantor set on the interval (0, 1) obtained by deleting the central 1/3, i.e., the interval (1/3, 2/3). Then repeat this operation with respect to the remaining segments an infinite number of times. In this case, increasing the linear size of the interval (0, 1/3) by a factor of 3 yields 2 copies of the same object. The resulting dimension is $D = \ln 2 / \ln 3 = .6309$. This indicates that the volume of a Cantor set increases by 63.09% given a doubling of each of its spatial dimensions.

A Whiteness Diagnostic Test

As discussed in the second section, traditional statistical tests may not distinguish between a random process and a deterministic chaotic process. However, Brock proposed a statistical test (the BDS test) to empirically analyze this distinction. The BDS test statistic is

$$(7) \quad W = T^{1/2}[C_m - (C_1)^m]/b_m,$$

where C_1 and C_m are given in (6) and b_m is the asymptotic variance of $[C_m - (C_1)^m]T^{1/2}$ (see Brock). Under the null hypothesis that x_t is an independent identically distributed (white noise) random variable, as $T \rightarrow \infty$, the W statistic in (7) converges to a standard normal variable with mean zero and variance one. Thus, the BDS test provides a statistical foundation for obtaining evidence against the null hypothesis that x_t is a white noise random process. Given the inability of more traditional statistical tests to distinguish between white noise and a deterministic but chaotic process, the BDS test can help uncover evidence of nonlinear dynamics. In particular, it can help detect misspecifications from using a linear model fit to nonlinear data.

The Residual Test Theorem

The results just discussed can be applied to any observable time-series x_t satisfying some weak regularity conditions. In applied work, the time series x_t is often assumed to follow a linear process that can be represented by an $AR(q)$ model of the form:

$$(8) \quad \beta_0 + B(L)x_t = e_t,$$

where $B(L) = \beta_1 L + \dots + \beta_q L^q$, L is a lag operator such that $L^s x_t = x_{t-s}$, β_0 is an intercept, and e_t is an innovation with mean zero and finite variance, h_t . Of particular interest here is Brock's theorem on the dynamic properties of the residual e_t in (8). Brock's residual test theorem states that, given a set of regularity conditions, the GP correlation dimension and the largest Lyapunov exponent of x_t and e_t are the same. This result suggests that the tools for analyzing nonlinear dynamics can be applied to the original data x_t , as well as to the innovations e_t associated with standard time-series models. This attractive characteristic increases the range of applications of the results discussed earlier. An empirical illustration of these tests and procedures is presented next.

An Application to the Pork Cycle

Here we investigate the nature of the U.S. pork cycle by analyzing the dynamics of the hog-corn price ratio. Quarterly observations on the U.S. hog-corn price ratio were obtained from various issues of *Livestock and Meat Statistics* for the period 1910–84. We first consider a typical linear time-series model where x_t , the hog-corn price ratio at time t , is assumed to follow an $AR(q)$ process as in (8), where e_t is normally distributed with mean zero and variance h_t . The order q of the AR process (8) was evaluated using Akaike's information criterion.

Equation (8) was estimated by the maximum likelihood method under two specifications: first, assuming that e_t is a homoscedastic white noise process where $h_t = h$, a scalar; and second, assuming that e_t follows a GARCH(1, 1) process where $h_t = a_0 + a_1 e_{t-1}^2 + a_2 h_{t-1}$ (Bollerslev).⁸ The Akaike criterion was minimized at $q = 20$. Table 1 presents the parameter estimates for an $AR(20)$ (where $h_t = h$), and for an $AR(20)$ with a GARCH(1, 1) error process. The estimates of $B(L)$ are similar in both instances. However, using a likelihood ratio test, the null hypothesis that $a_1 = a_2 = 0$ is rejected at the 5% level. Thus, statistical evidence indicates that the error term e_t is not homoscedastic and that its variance h_t is changing over time.

Following Luenberger (p. 96), the expected value of (3) can be expressed as an equivalent system of first-order difference equations: $X_t = HX_{t-1}$. The characteristic roots of the companion matrix, H , provide useful information about the dynamics of the estimated model (8). Details about the characteristic roots for both the estimated $AR(20)$ and the $AR(20)$ -GARCH(1, 1) models are presented in table 2. The results in table 2 indicate that both estimated models are dynamically stable and have cycles with periods ranging from one to five years. These results are consistent with previous research on cycles in the pork market (e.g., Wallis, Bessler and Kling Kaylen). Moreover, the presence of multiple cycles is also consistent with the results obtained by Talpaz.

To check the validity of the estimated versions of model (8), several standard tests were performed on the estimated residuals, e_t . The Box-Pierce test examines the estimated resid-

⁸ GARCH stands for "generalized autoregressive conditional heteroscedasticity."

uals for white noise.⁹ The white noise test proposed by Ljung and Box is a modification of the first test.¹⁰ Last, McLeod and Li proposed a test for white noise which is based on the squared-residual autocorrelations of ϵ_t .¹¹ This test is use-

⁹ The Box-Pierce Q_a and the Ljung-Box Q_a^* tests are based on the residual autocorrelation function:

$$r_a(k) = \frac{\sum_{t=k+1}^T \epsilon_t \epsilon_{t-k}}{\sum_{t=1}^T \epsilon_t^2},$$

where the ϵ_t are the innovations associated with equation (8). Under the null hypothesis that the residuals are white-noise, the Box-Pierce statistic

$$Q_a = T \sum_{i=1}^m r_a^2(i)$$

is distributed approximately as a $\chi^2(m - q)$.
¹⁰ Ljung and Box proposed to use the statistic

$$Q_a^* = T(T + 2) \sum_{i=1}^m r_a^2(i) / (T - i),$$

which is approximately distributed as a $\chi^2(m - q)$ under the null-hypothesis of white noise.

¹¹ The squared-residual autocorrelation function is given by

$$r_{aa}(k) = \frac{\sum_{t=k+1}^T (\epsilon_t^2 - \sigma^2)(\epsilon_{t-k}^2 - \sigma^2)}{\sum_{t=1}^T (\epsilon_t^2 - \sigma^2)^2},$$

where

Table 2. Dynamics Associated with the Characteristic Roots of H

^a The period is denoted in years.
^b These are real roots and hence do not exhibit cyclical behavior.

$$\sigma^2 = \sum_{t=1}^T \epsilon_t^2 / T.$$

McLeod and Li show that, under white noise, the statistic

$$Q_{aa} = T(T + 2) \sum_{i=1}^m r_{aa}^2(i) / (T - i)$$

is asymptotically distributed as a $\chi^2(m)$.

ful for detecting certain types of nonlinear statistical dependence in time-series residuals.

The above tests were used to determine whether the AR(20) residuals in (8) are white noise for $m = 40$. The test statistics were 23.34 and 26.49 for the Box-Pierce and Ljung-Box tests, respectively. Given a critical value of 31.41 from the asymptotic chi-square distribution at the 5% level, the null hypothesis that the residuals of (8) are white noise cannot be rejected in either case. Alternatively, the test statistic for the McLeod-Li test was 40.06. Given a critical value of 55.76 from the asymptotic chi-square distribution at the 5% level, the hypothesis that second-order autocorrelation is present in the residuals, e_t , also is rejected. Similar results were obtained for the standardized residuals from the AR(20)-GARCH(1, 1) model.¹² These tests suggest that the linear model (8) (with either homoscedastic errors or with GARCH errors) appropriately represents price dynamics in the hog market.

Now consider the BDS test. Choosing $m = 40$, the W statistics (7) were calculated for the original data x_t , for the AR(20) residuals in (8), and for the standardized residuals of the AR(20)-GARCH(1, 1) model. The results are reported in table 3 for selected values of ϵ . Recall that under the null hypothesis of white noise, W converges asymptotically to $N(0, 1)$. Thus, the critical value of the W test at the 5% level is 1.96.

The results in table 3 indicate that the null hypothesis that x_t is white noise is strongly rejected. The W statistics also provide statistical evidence that the AR(20) residuals are not, in fact, white noise. Given the results of the more

traditional tests for white noise, it follows that obtaining significant W statistics for the residuals of (8) provides important evidence of model misspecification caused by fitting a linear model to data generated by a nonlinear process. Moreover, these results are consistent with those of Brock and Sayers in their analysis of business cycles.

The BDS test applied to the standardized residuals from the AR(20)-GARCH(1, 1) model is also of interest. First, the evidence against white noise is not as strong as for the AR(20) residuals (see table 3). This result indicates that the GARCH specification is perhaps capturing some of the nonlinearities of the dynamic process. Second, for high values of ϵ , the BDS test still indicates that the standardized AR(20)-GARCH residuals are not white noise. Thus, the existence of nonlinear dynamics in the pork cycle cannot be fully explained by the GARCH error process. Importantly, this evidence for nonlinearities indicates that fundamental asymmetries may exist between the expansion phase and the contraction phase of the hog cycle.

Given that the hog-corn price ratio is associated with nonlinear dynamics, evidence on the nature of the underlying dynamic process also can be obtained by measuring the GP correlation dimension and the largest Lyapunov exponent. Brock and Sayers proposed using

$$(9) \quad SC_m(\epsilon_i) = (\ln C_m(\epsilon_i) - \ln C_m(\epsilon_{i-1})) / (\ln(\epsilon_i) - \ln(\epsilon_{i-1}))$$

as an empirical estimate of the GP correlation dimension, where C_m is defined in (6). The dimension estimates, SC_m , are reported in table 3 (using $m = 40$) for the hog-corn price ratio x_t ,

¹² The standardized residuals for the AR(20)-GARCH(1, 1) model are given by $e_t h_t^{-1/2}$, where h_t is the conditional variance.

Table 3. Dimension Estimates (SC_m) and BDS White Noise Test Statistics (W)

Note: All results are obtained for $m = 40$.

for the AR(20) residuals in (8), and for the standardized residuals of the AR(20)-GARCH(1, 1) model. The dimension estimates for x_t are rough: they can be as high as 9. The dimension estimates for both e_t from the AR(20) model and $e_t h_t^{-1/2}$ for the AR(20)-GARCH(1, 1) model are also rough but tend to be higher: they can be as high as 25. Based on the GP dimension estimates, the underlying dynamic process appears complex and would probably not be adequately represented by just a few state variables.

Last, given the evidence of nonlinearity provided by the BDS test, is there any evidence of chaotic behavior in the pork cycle? This question is investigated by calculating the largest Lyapunov exponent, λ_1 , using Wolf et al.'s algorithm.¹³ The estimates of λ_1 were positive: .0041 for x_t and .0038 for the AR(20) residuals. Thus, the estimates of λ_1 are in the chaotic region. Their small magnitude indicates that the rate of divergence of neighboring paths is low. Thus, the pork cycle may still be predictable in the short- and intermediate-run, even if chaotic. Only in the longer run may neighboring paths diverge and, hence, become unpredictable. Finally, the estimates of λ_1 are close to the non-chaotic region ($\lambda_1 < 0$). Because the statistical properties for the estimator of λ_1 are currently unknown, we cannot conclude there is strong evidence of chaos in the dynamics of the hog-corn price ratio.¹⁴

Conclusions

The results provide clear evidence that the dynamic process generating the pork cycle is, in fact, nonlinear; however, the evidence in favor of "chaos" is less conclusive. The results of this study also suggest that linear time-series models commonly used to analyze pork market dynamics (e.g., Wallis; Shonkwiler and Spreen; Bessler and Kling; Kaylen) may fail to fully capture economic dynamics. Furthermore, while GARCH error processes can account for some of the nonlinearities, the pork market appears to be characterized by other forms of nonlinear dynamics. In addition, the empirical estimates of the GP correlation dimension show that the nature of nonlinear dynamics in the pork market are complex and cannot be represented by a few state

variables. Although little a priori information is available about the exact source of these nonlinearities, fundamental asymmetries likely exist between the expansion and contraction phases of the pork cycle. Consequently, structural models are needed to provide useful information on this issue. The dynamics of entry and exit in the pork industry and its implications for supply response are promising topics for future research.

Finally, if the existence of the pork cycle requires that the cycle is not perfectly predictable (as argued in the introduction), the source of this unpredictability remains unclear. Although our results present some evidence in favor of chaos that could explain the unpredictability of the pork cycle, this evidence is not definitive. Further work is needed to assess whether chaos can help us better understand the dynamics of agricultural markets.

State-Space Modeling of Cyclical Supply, Seasonal Demand, and Agricultural Inventories

Jeffrey H. Dorfman and Arthur Havenner

The production of certain agricultural products follows an alternate bearing pattern of large and small crops. Many agricultural products also experience seasonal shifts in demand. Such patterns present a natural opportunity for profitable inventories. This paper applies state-space modeling techniques to the problem of modeling cyclical patterns in supply and demand and presents an application to the determination of inventory levels for such agricultural products using linear quadratic control.

Key words: alternate bearing, inventories, olives, optimal control, seasonality, state-space models.

The production of certain agricultural products follows an alternate bearing pattern of large and small crops. While many agricultural products exhibit this pattern, the more famous examples are tree crops, including apples, almonds, pecans, and olives. A physiological process in the trees causes a high-yield year to be followed by a low-yield year. Such a two-year cycle will continue until some outside event, usually weather related, breaks the cycle. For example, if in a year that should have been a high yield year there is bad weather during a crucial stage of the fruit's development, a small crop may result. High yields then are expected in the year following this weather event, beginning another cyclical pattern. Because these two-year cycles are initiated by weather phenomena, all the trees in a given area tend to be on the same two-year pattern, leading to wide fluctuations in crop production for alternate bearing crops, especially those produced within a single region. Pomologists strive to reduce these yield swings and

have succeeded to some extent through fertilization, irrigation, and pruning. However, many agricultural products still have pronounced alternate bearing cycles.

The demand for many agricultural products also displays cyclical patterns related to seasonal changes in taste. Even with the recent availability of imported products virtually year-round, consumers prefer certain goods more at particular times of year. Dummy variables are too abrupt to smoothly track seasonal fluctuations in the demand schedule. A more general method of tracking such cyclical patterns in supply and demand is desirable.

This paper presents several new methods for analyzing cyclical products. It is shown that state-space models can be used successfully to model cyclical patterns in both supply and demand. Then, we demonstrate how state-space models can be inserted into the familiar linear quadratic control framework, allowing the supply and demand estimates to be employed in the determination of optimal inventory levels for such products. This will be done by applying techniques of econometrics, linear systems theory, and optimal control with an empirical example based on the California canned olive industry.

The first part of the paper briefly describes the linear systems theory approach to constructing an approximate state-space model. The second and third parts of the paper present the olive supply and demand functions which are used to forecast future production and demand for use in making inventory decisions. State-space

Jeffrey H. Dorfman is an assistant professor, Department of Agricultural Economics, University of Georgia; Arthur Havenner is a professor, Department of Agricultural Economics, University of California, Davis.

This paper is Faculty Series Paper No. 90-21 of the Division of Agricultural Economics, University of Georgia, and Giannini Foundation Paper No. 959. The research was partially supported by a Giannini Foundation grant and by Hatch Project No. H-605 of the Georgia Agricultural Experiment Station.

The authors wish to thank Desmond Jolly for helpful comments and invaluable assistance in obtaining data. The paper was also improved by comments from Masanao Aoki, Jean-Paul Chavas, Roger Craine, Ben French, Gordon King, and two anonymous referees. Any remaining errors are, as usual, the fault of the authors.

models are used in both cases. Finally, the fourth section develops the optimal control model, employing the linear quadratic framework popularized in economics by Chow. The control model produces recommendations on both absolute price levels and relative prices among the different grades.

Linear Systems Theory Estimates of State Space Models

Because the supply and demand curves of canned olives will be modeled using a particular state-space time-series procedure, the estimators of this state-space system are developed and briefly discussed below. This approach, a version of multivariate time-series analysis, emphasizes dynamic rather than static relations between variables. It uses results from the engineering literature on dynamic approximations to determine the model specification most consistent with the observed data in a formal approximation sense and has produced accurate forecasts in other contexts; see Aoki and Havenner for a survey with applications. Accurate forecasts are important in setting inventory levels with alternate bearing crops because the solution must look forward over two crop years and, using the monthly data employed here, twenty-four months of demand.

The state-space model consists of two matrix equations: the state equation,

$$(1a) \quad z_{t+1|t} = Az_{t|t-1} + Be_t,$$

and the observation equation,

$$(1b) \quad y_t = Cz_{t|t-1} + e_t,$$

where y_t is an $(m \times 1)$ vector of observations on the series to be modeled, e_t is an $(m \times 1)$ vector of stochastic innovations assumed to be i.i.d. with a zero mean, and $z_{t|t-1}$ is an $(n \times 1)$ vector of conditional means of the states, or minimal sufficient statistics for the past history of the series y_t . The subscripts on $z_{t|t-1}$ denote a conditional expectation of the state for time period t given the information set of time period $t-1$. The matrices A , B , and C are parameters to be estimated.

The innovations e_t appear in both equations. Because the states are defined to be minimally sufficient statistics for the series y_t , when a new observation occurs the states must be updated. The only new information in y_t is contained in

the innovation e_t . The matrix B serves to combine this new information into the states in a manner such that the states remain minimal sufficient statistics for the series y_t as long as the innovations are assumed to come from a distribution with the linear inheritance property (such as the normal distribution). For a detailed description of the relationship between state-space models and ARIMA models, see Aoki and Havenner.

Beginning the model estimation process, let the upper bound on the number of lags needed to model y_t be p and the desired forecast horizon be h . Define the $(mf \times 1)$ and $(mp \times 1)$ future and past data vectors as $y_t^+ = (y_t', y_{t+1}', \dots, y_{t+f-1}')$ and $(y_t^- = (y_t', y_{t-1}', \dots, y_{t-p+1}')$. The autocovariance matrix that allows the prediction of y_t^+ from y_{t-1}^- can now be defined as $H = E(y_t^+ y_{t-1}^-')$ and estimated as

$$(2) \quad \hat{H} = \begin{bmatrix} \hat{\Gamma}_1 & \hat{\Gamma}_2 & \hat{\Gamma}_3 & \dots & \hat{\Gamma}_p \\ \hat{\Gamma}_2 & \hat{\Gamma}_3 & \hat{\Gamma}_4 & \dots & \hat{\Gamma}_{p+1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \hat{\Gamma}_f & \hat{\Gamma}_{f+1} & \hat{\Gamma}_{f+2} & \dots & \hat{\Gamma}_{f+p-1} \end{bmatrix},$$

where each $\hat{\Gamma}_i$ is estimated by the standard, maximum likelihood sample autocovariance formula

$$(3) \quad \hat{\Gamma}_i = T^{-1} \sum_{t=1}^{T-i} y_{t+i} y_t' \quad i = 0, 1, \dots, p+f,$$

where T is the sample size. The $\hat{\Gamma}_0$ and $\hat{\Gamma}_{f+p}$ matrices do not appear in \hat{H} , but are used later. The choice of the letter H for the autocovariance matrix is the result of its being a Hankel matrix—a block band counterdiagonal matrix.

In order to estimate the model coefficients, two matrix decompositions of the Hankel matrix will be employed. The singular value decomposition of \hat{H} is

$$(4) \quad \hat{H} = \hat{U} \hat{\Sigma} \hat{V},$$

with $\hat{U}'\hat{U}$ and $\hat{V}'\hat{V}$ identity matrices and $\hat{\Sigma}$ a rectangular matrix with the singular values along the "diagonal" beginning at the top left corner and zeros elsewhere. When estimating a model with n states, only the n -largest singular values are used. Setting the smallest singular values to zero constitutes the set of exclusion restrictions used to identify the model, equivalent to the restrictions on which lagged observations and errors have zero coefficients in an ARMA model. Denote the approximate Hankel matrix, created by replacing $\hat{\Sigma}$ with a matrix of only the n -largest

est singular values (with the other singular values set to zero), by \hat{H}_n , and the singular vector decomposition of \hat{H}_n by

$$(5) \quad \hat{H}_n = \hat{U}_n \hat{\Sigma}_n \hat{V}_n.$$

In order to derive estimators of the coefficients it is important to recognize the following pattern in the individual autocovariance submatrices of H ,

$$(6) \quad \Gamma_i = E y_{t+i} y_t' = C A^{i-1} \Omega,$$

where $\Omega = E(z_{t+1} y_t')$. This relation can be established using the model in (1) and the above definition of Ω . Recognition of this pattern allows a factorization of the Hankel matrix into its observability and controllability matrices, O and K .

$$(7) \quad H = OK = \begin{bmatrix} C \\ CA \\ \vdots \\ CA^{p-1} \end{bmatrix} [\Omega \ A \Omega \ \dots \ A^{p-1} \Omega].$$

The two different factorizations of the Hankel matrix can be equated to give

$$(8) \quad \hat{H}_n = \hat{U}_n \hat{\Sigma}_n \hat{V}_n = \hat{O}_n \hat{K}_n.$$

Equating these factorizations specifies the model and allows a solution for estimators. Let \hat{H}_1 and $\hat{H}_{\cdot 1}$ represent the first m rows and the first m columns of \hat{H} , and note the following relationships from the first block row and block column of (7) above:

$$(9) \quad H_{1\cdot} = [\Gamma_1 \ \Gamma_2 \ \Gamma_3 \ \dots \ \Gamma_p] = CK,$$

$$(10) \quad H'_{\cdot 1} = [\Gamma_1' \ \Gamma_2' \ \Gamma_3' \ \dots \ \Gamma_p'] = \Omega' O'.$$

These two equations constitute the first-order conditions for the estimators of C and Ω . The estimates of C and Ω are therefore given by

$$(11) \quad \hat{C} = \hat{H}_1 \hat{K}_n^-, \text{ and}$$

$$(12) \quad \hat{\Omega} = \hat{O}_n^- \hat{H}_{\cdot 1},$$

where \hat{K}_n^- and \hat{O}_n^- are generalized inverses defined as

$$(13) \quad \hat{K}_n^- = \hat{V}_n (\hat{\Sigma}_n)^{-1/2}, \text{ and}$$

$$(14) \quad \hat{O}_n^- = (\hat{\Sigma}_n)^{-1/2} \hat{U}_n'.$$

To estimate A , it is necessary to introduce a time-shifted autocovariance matrix, \tilde{H} , defined as

$$(15) \quad \tilde{H} = \begin{bmatrix} \Gamma_2 & \Gamma_3 & \Gamma_4 & \dots & \Gamma_{p+1} \\ \Gamma_3 & \Gamma_4 & \Gamma_5 & \dots & \Gamma_{p+2} \\ \vdots & \vdots & \vdots & \text{xxx} & \vdots \\ \Gamma_{f+1} & \Gamma_{f+2} & \Gamma_{f+3} & \dots & \Gamma_{f+p} \end{bmatrix} = OAK.$$

The left arrow notation is motivated by interpreting \tilde{H} as a Hankel matrix with the blocks of H shifted left one position and then the last column filled on the right. The second equality in (15) comes from placing A in the middle of (7) and using the relations in (6). The estimate of A is derived by applying the generalized inverses of \hat{K}_n and \hat{O}_n again, yielding

$$(16) \quad \hat{A} = \hat{O}_n^- \hat{\tilde{H}} \hat{K}_n^-.$$

The generalized inverses used for O and K determine the scale of the states and, thus, the coefficients. They were chosen so that $\hat{K}_n \hat{K}_n' = \hat{O}_n' \hat{O}_n = \hat{\Sigma}_n$. This scaling is known as the balanced representation, resulting in the coefficients in \hat{A} , $\hat{\Omega}$, and \hat{C} being uniquely identified. While other scalings could have been selected, by calculating \hat{A} , $\hat{\Omega}$, and \hat{C} from the n nonzero singular values in $\hat{\Sigma}_n$ and the orthogonal singular vectors of \hat{U}_n and \hat{V}_n subject to the balanced representation, the estimates possess the property referred to as being "strictly nested." The estimates are called "strictly nested" because the leading principal submatrices of \hat{A} , $\hat{\Omega}$, and \hat{C} contain the exact numerical values that would be produced by the model if it were estimated with the correspondingly smaller number of nonzero singular values. This result occurs because these estimates are composed of parts of scaled singular vectors (which are, of course, orthogonal). Also, since the singular values are included in decreasing order, any states left out (by too small an n) are less important than each of the included states. Thus, if additional states (associated with additional singular values) are included incorrectly in the model, all coefficients of the true model are estimated consistently and, in fact, are numerically identical to the estimates that would be obtained from the correct specification (hence the adjective "strictly"). Alternatively, if states (and associated singular values) of the true model are excluded from the estimated model, the coefficients that are included are again consistently estimated and the included states are the most important ones in the determination of the series being modeled. This has important consequences in model specification. For a detailed

proof of the strict nesting property see Havenner and Criddle.

With estimates of A , C , and Ω in hand, we can develop an estimate of the Kalman filter matrix, B . This is done by solving a system of three matrix equations involving four covariances: the state covariance matrix, $\Xi = E(z_{t+1}|z_{t+1}|')$; the error covariance matrix, $\Psi = E(e_t e_t')$; the covariance of the states with the series, $\Omega = E(z_{t+1}|y_t')$; and the unconditional data covariance matrix, $\Gamma_0 = E(y_t y_t')$. In presenting these equations in as simple a manner as possible, use has been made of the orthogonality of the current states, z_{t-1} , and the innovations, e_t . The first two equations are derived by taking the expectations of equations (1a) and (1b) postmultiplied by their own transposes:

$$(17) \quad \Xi = A\Xi A' + B\Psi B',$$

$$(18) \quad \Gamma_0 = C\Xi C' + \Psi.$$

Taking the expectation of the state equation (1a) postmultiplied by the transpose of the observation equation (1b) gives the third matrix equation,

$$(19) \quad \Omega = A\Xi C' + B\Psi.$$

Based on the previously developed estimators of A , C , Γ_0 , and Ω estimates of B , Ξ , and Ψ can be obtained by solving (17) through (19) simultaneously. Methods for solving equations (17) through (19) are found in Aoki and Havenner, and in Aoki.

With the estimates of A , B , and C that have now been derived an estimate of the initial state vector z_0 can be obtained by backcasting; for details see Aoki. Given this conditional estimate of the initial states of the system, the model given by (1) can be solved for in-sample and out-of-sample forecasts.

The Supply Model

Olive trees mature slowly and live for a long time. A tree begins bearing a crop in its seventh or eighth year, reaches full maturity at about twenty, and often produces at a profitable level up to age fifty. In the United States, commercial olive production occurs only in California. Olive bloom and fruit set occur in May, so rain does not generally present a problem with pollination and is therefore not an important factor in the determination of supply. The harvest of olives in California begins in September and ends in October or November, depending on weather

and variety. Recent acreage changes have been slightly downward (2%–3% per year), which seems to be a correction for an earlier too rapid expansion (Jolly).

The production of olives in California has varied from 5.4 to 14.3 million cases in the last ten years (California Olive Committee). Year-to-year variation has exceeded 100%. This variation is partly caused by olives being an alternate bearing crop. Pomologists associate this phenomenon with the heavy drain on the trees' nutrients during the high yield year and the subsequent small production of new fruiting wood for the next bloom period (Hartman and Opitz). This cycle within the stochastic nature of the supply of olives can be exploited for more accurate forecasting of future supplies. The main product of California olives is canned, ripe olives, with over 90% of the crop being canned. These canned olives are differentiated by size.

The supply model is concerned with predicting the supply of canned California olives in five size classes. The long lag between planting and production allows the supply to be modeled without acreage as an exogenous variable because it changed very little in the time studied and cannot change much over a two-year planning horizon. Further, supply will be modeled without price as an exogenous variable because, while the price level affects profitability and, therefore, the number of acres of olives, price has little effect on the current year's supply. As long as price is high enough to cover harvesting costs, producers will harvest their crop and cannot increase production (except, perhaps, by reducing waste) in response to a high current price.

The supply model was formulated with the five main size classes of canned olives used by the California olive industry (small, medium, large, jumbo, and colossal). Thus, supply is modeled as the joint production of five varieties of canned olives. While this ignores those olives produced but not canned and some olives that fall into a few other categories, such a formulation captures about 80% of the olives produced in California.

Structuring the optimal control model around these size classes provides two advantages. On the demand side, prices of canned olives vary by size class. By not combining all the sizes into one single product, an aggregation problem is avoided and information is preserved. On the supply side, more accuracy can be achieved without overtaxing a short data series. The supply model has a very short time series—nine annual observations. The California olive in-

dustry experienced such large growth in the early and mid-1970s that to go farther back in time would introduce structural change to the system.

With other time-series methods, this short time series could signal the end of the empirical analysis; but, with a state-space model, the shortage of data can be compensated for by the inclusion of multiple series driven by shared states. The data support our a priori conjecture that the states that determine the supply of one size of olives will be the same as, or closely related to, the states that determine the supply of other sizes, although the effects on the various sizes differ. In the empirical approximation of the model, having five series allows a higher-order determinantal polynomial to be fit to each series without utilizing the data from each series too intensively. This is because the order of the determinantal polynomial is bounded by the product of the number of series, m , and the number of lagged periods in the y_t vector, p . As the lag parameter p increases, fewer observations are available to calculate the additional estimated autocovariances [see (4)]. Therefore, the five series employ more observations in approximating the Hankel matrix (potentially resulting in greater accuracy) while not restricting the model to a specification with insufficient flexibility.

The supply model in state-space form is

$$(20) \quad z_{t+1|t} = A_s z_{t|t-1} + B_s e_t$$

$$(21) \quad y_t = C_s z_{t|t-1} + e_t$$

where y_t is a (5×1) vector of the supply of the five sizes of canned olives in year t and the s subscripts differentiate these matrices from those of the demand model which follows. The model was estimated using the years 1977 through 1985. The series were all centered and divided by standard deviations to have zero means and un-

conditional variances equal to one. This makes the mean-squared errors comparable across series. To keep the determinantal polynomial equation to a suitably low order for an annual time series of olive production, the lag parameter, p , was set to one. This allows up to a fifth-degree determinantal polynomial. It also preserves observations in the estimation of the autocovariance matrices.

The best approximation occurred with two states ($\hat{n} = 2$). The mean-squared errors for the predictions of the five series ranged from .404 to .732, which are fairly good—although not outstanding—when compared to the series' unconditional variances of unity. The estimates of the A_s , B_s , and C_s matrices are given in table 1, along with the mean-squared errors and R^2 of each of the five series. The dynamics matrix A_s has two real eigenvalues, -0.588 and 0.191 . The absolute values of both roots are less than one, implying that the system is stable. The negative eigenvalue captures the alternate bearing phenomenon by introducing a "sawtoothed" oscillation to the supply model's dynamics. Because each eigenvalue of A_s has a modulus less than one, the alternate bearing cycle would die out if it were not restarted by new exogenous weather shocks.

The Demand Model

Because California canned olives have few, if any, close complements or substitutes, the demand side of the industry also will be modeled as a state-space system with the addition of a structural equation. This allows the emphasis of the modeling to be placed on the dynamics of the system rather than on cross relations with other variables. For a product without any strong cross relations (elasticities of substitutions close

Table 1. Supply Model Parameters

	Small	Medium	Large	Jumbo	Colossal
MSE	.436	.404	.546	.732	.508
R^2	.707	.768	.570	.451	.545
A_s	-.487 -.264	-.259 .0906			
B_s	2.11 .473	-1.77 -.00804	.986 -1.97	.089 1.37	-.950 .162
C_s'	-.772 .160	-.859 .038	-.343 -.320	-.531 -.105	.0174 -.536

to zero), this is advantageous. The five sizes of California olives will again be treated as separate time series. For the demand system, though, the period of observation is one month, not a year as in the supply model. This allows seasonal cycles in demand to be traced. Such cycles are very important in olives, which have two high demand and two low demand seasons per year. Thus, a vector of demand for olive products will be estimated and forecast.

Because prices are the control variables in the optimal control model (see below), demand will be estimated with sales levels as the dependent variables and prices as an exogenous variable. The presence of exogenous (known and observable) variables, such as prices, requires that the state-space system be augmented with a regression equation in order to remove the time-varying deterministic mean ($\alpha + \beta p_t$) from the series of quantities demanded, thus rendering the resulting series stationary.

The demand system can be written as

$$(22) \quad z_{t+1|t} = Az_{t|t-1} + Be_t$$

$$(23) \quad u_t = Cz_{t|t-1} + e_t$$

$$(24) \quad q_t = \alpha + \beta p_t + u_t,$$

where q_t is a (5×1) vector of the quantity sold in month t and p_t is a (5×1) vector of the wholesale prices of the five sizes of olives. Obviously, the state vector $z_{t|t-1}$ and the innovations e_t differ from those in the supply model. This demand system was estimated using a monthly series from 1983:7 to 1987:6, saving 1987:7 to 1988:6 for out-of-sample validation. Although no prices of other goods enter the demand system, the prices of all five olive size classes are in each size's demand function. This is because there are extensive possibilities for substitutability and complementarity in demand between olive size classes.

Equations (22) through (24) were estimated by an iterative procedure. First, equation (24) was estimated by least squares. Then, using the resulting residuals, \hat{u}_t , as the observation series, (22) and (23) were estimated by the process outlined above. This process allows the construction of an updated \hat{u}_t series using the forecasts of the state-space model. The state-space model's forecasts were then used to generate a q^* series where $q_t^* = q_t - \hat{u}_t$, and \hat{u}_t is now the forecasts from (22) and (23). The structural parameters α and β were then reestimated using q^* instead of q and the process continued until the parameters converged.

The results of the estimation of the demand system in (22) through (24) are presented in table 2. The sales quantities are measured in thousands of cases. In table 2, B has been multiplied by 10^3 in order to simplify the table. Further, the mean-squared errors are normalized by each series' unconditional variance to provide a natural scale for these statistics. The MSE and R^2 statistics show that for all the size classes except the colossal a reasonable reduction in the variation of the series was obtained. The magnitude of the off-diagonal elements of β indicate that cross relations between size classes are indeed important. In fact, complementarity exists among several of the sizes; in particular, the two smallest sizes (small and medium) are complements to the three larger sizes (as can be seen by the negative terms below the diagonal in the first two columns of β). This is not surprising given the large sales of canned olive to the food service industry, where olives are used in salads and other dishes in either chopped or sliced form and only a few of the larger sized olives are employed as a decoration. While there is one positive own-price effect (for the large class), this coefficient is not significantly different from zero.

Model validation was done using a procedure from Henriksson and Merton. This procedure measures the confidence level of the hypothesis that the forecasts contain information value. This is equivalent to testing if the model can forecast the direction of revision in the series. The results of testing all five size classes together were confidence levels of 0.997 in-sample and 0.605 for the twelve out-of-sample observations. For further details see Dorfman.

The Optimal Control Model

The optimal control model is formulated as if the Olive Marketing Board could set wholesale prices for the industry. The Olive Marketing Board is comprised of grower, processor, consumer, academic, and government representatives. It is governed by a set of regulations approved by its member growers and processors under laws set up from the 1922 Capper-Volstead Act onward. While the Olive Marketing Board does not currently have the power to set prices, such power could be bestowed upon it by the vote of a suitable majority of the growers and processors. Seven processors buy essentially the entire crop of California olives from the growers, process the olives, and sell the resulting products to either food service compa-

nies, other food processors, or retailers. Thus, the number of firms that would be involved in an inventory control program is a manageable number.

The objective function proposed for the inventory optimal control model is inspired by Vinod. He refers to models with objective functions of this type as "eclectic," implying that they attempt to mimic decision makers with multiple objectives. We propose three objectives for the regulation of olive inventories, with weights that determine their relative importance to the decision makers.

A major motivation for inventory control is to attempt to improve profit by more efficient temporal allocation of the available supply. Hence, the first term of the objective function is discounted revenues. The costs of production can be safely ignored here because the date of sale does not affect these costs. Storage costs are accounted for by adjusting the discount rate employed to reflect the percentage of the price that represents the cost of storing the canned olives.

The second objective is price stability. Both Massell and Samuelson have shown that the sum of producer and consumer surplus is higher under stable prices than instable prices. The results of Waugh, showing that consumers should favor price instability, and Oi, demonstrating a similar result for producers, result from a form of price instability that causes a more than offsetting loss to the producers or consumers, respec-

tively. When both sides of the market are considered simultaneously, price stability is welfare increasing.

In the work most familiar to agricultural economists, Newbery and Stiglitz caution against the use of consumer surplus to measure consumer welfare under various price stabilization schemes, pointing out that the Hicksian demand curve is the appropriate one to examine. Newbery and Stiglitz show that at least some degree of price stabilization, accomplished by the holding of inventories, is beneficial given reasonably low storage costs. In particular, when such stabilization does not have a significant effect on supply, as would be the case for olives with a highly price inelastic short-run supply function, Newbery and Stiglitz demonstrate that price stabilization has a net positive benefit. Craine also shows that in a general equilibrium framework stable prices are welfare increasing.

Because the marketing board represents growers and processors, this price stability term makes sense. This term also serves to discourage the regulators from "overmanaging." A term representing consumers' desire for low prices is unnecessary since the demand curves enter the optimization problem as a set of constraints.

The third objective is a desired sales level. Sales are encouraged to approximately match target levels, with a penalty for squared deviations of sales from the targets. This specification is not equivalent to a feasibility constraint (which is included in the constraint set, not in

the objective function). A feasibility constraint simply assures that sales do not exceed the sum of production and carry-in inventories.

The industry has been building up substantial inventories over the past several years with current inventory levels of approximately one-half of annual production. If storage levels continue to climb, the growers are certain to find themselves in an increasingly unfavorable negotiating position relative to the processors. The examination of these storage levels was the motivation for including desired sales levels in the objective function.

Defining ρ as the discount factor inclusive of both normal opportunity costs and storage costs, the inventory control problem is to

$$(25) \quad \min_{\{p\}} \mathcal{L} = - \sum_{t=1}^T \rho^t p'_t q_t + \sum_{t=1}^T (p_t - p_{t-1})' R_t (p_t - p_{t-1}) \\ + \left(\sum_{t=1}^T q_t - d^* \right)' S \left(\sum_{t=1}^T q_t - d^* \right),$$

subject to

$$(26) \quad z_{t+1|t} = Az_{t|t-1} + Be_t,$$

$$(27) \quad u_t = Cz_{t|t-1} + e_t,$$

$$(28) \quad q_t = \alpha + \beta p_t + u_t, \text{ and}$$

$$(29) \quad \sum_{t=1}^T q_t \leq s + k.$$

In the criterion above, the matrices R_t and S are specified by the decision makers to match their objectives, the vector d^* is the goal chosen for sales over the model period, s is a vector of production over the model period, and k is a vector of carry-in stocks. The subscript t refers to monthly time periods and T is set at 24 for the empirical solution of the model. The choice of a two-year period is based on the two-year alternate bearing cycle that olive trees follow. This natural physiological phenomenon makes one complete alternate bearing cycle an obvious choice for inventory planning horizon. Thus, the demand system of equations (26) through (28) serves as the equations of motion, while (29) is the set of feasibility constraints limiting sales to production plus carry-in inventories.

The discount parameter ρ reflects both the actual storage costs of the canned olives and the opportunity cost of waiting an additional month to sell them. The interest rate for one-month certificates of deposit of \$100,000 and over was employed. The control problem is solved for the

two-year period 1985–86. For the first week of January 1985, the interest rate was 8.1%. A reasonable estimate of storage costs was obtained from industry sources and set at 0.5% per month of the price of olives. This constant percentage markup for storage costs is reasonable because the storage facilities are sunk costs and the only other nonnegligible cost is the interest on the loans that processors use to finance themselves until the olives are sold. This can be added to the interest on the money that would have been earned by selling the olives to arrive at a total discount factor. Thus, for the 1985–86 period, the discount factor $\rho = 1/(1 + (.081/12) + .005) = 0.988$.

Because it is the relative weights of the three

terms of the objective function that determine the result, not their absolute values, the weight on the revenue term is normalized to unity. The matrices R_t and S are the relative weights for the price and feasibility terms, respectively. While they need not be diagonal in general, R_t and S will be assumed diagonal here.

The inventory control problem is solved as a deterministic closed-loop optimal control problem. It is simplest to rewrite the problem in terms of a model augmented to first order with a quadratic loss function. This can be done, paying careful attention to the dynamics embodied in the Kalman filter matrix B and to which innovations are observable in each time period. If (27) and (28) are combined and the state equation is backdated one time period, the result is a seven-equation demand model written in matrix form as

$$(30) \quad z_{t|t-1} = Az_{t-1|t-2} + Be_{t-1}$$

$$(31) \quad q_t = \alpha + \beta p_t + Cz_{t|t-1} + e_t.$$

Next, backdate (31) one period and solve for the innovation e_{t-1} in terms of q , p , and z . Substitute this expression into the right-hand side of (30) to replace the known innovation e_{t-1} . This results in equation (32) below. Then, replace the $z_{t|t-1}$ in (31) with the expression on the right-hand side of (32) and replace the unknown innovation e_t with its zero expectation. This substitution gives a new observation equation shown in (33). The result is the state-space model written in a deterministic augmented first-order form

with the dynamics of the Kalman filter preserved,

$$(32) \quad \begin{aligned} z_{t|t-1} &= Az_{t-1|t-2} + B(q_{t-1} - \alpha - \beta p_{t-1} - Cz_{t-1|t-2}) \\ &= Bq_{t-1} + (A - BC)z_{t-1|t-2} - B\alpha - B\beta p_{t-1} \end{aligned}$$

$$(33) \quad \begin{aligned} q_t &= \alpha + \beta p_t + C[Az_{t-1|t-2} + B(q_{t-1} - \alpha - \beta p_{t-1} - Cz_{t-1|t-2})] \\ &= CBq_{t-1} + C(A - BC)z_{t-1|t-2} + (I - CB)\alpha + \beta p_t - CB\beta p_{t-1}. \end{aligned}$$

The augmentation of the model necessary to write the problem with a quadratic loss function and a first-order model is straightforward. Three new variables are defined in the augmentation to first order. The variables x and v are both renamings of the price variable: $v_t \equiv p_t$ and $x_t \equiv p_{t-1}$. The variable d_t is defined by $d_t \equiv (\sum_{s=1}^t q_s - d^*)$, remembering that d^* is the desired sales over the planning horizon. The augmented model is

$$(34) \quad \bar{y}_t = \begin{bmatrix} q_t \\ z_{t|t-1} \\ v_t \\ x_t \\ d_t \end{bmatrix} = \begin{bmatrix} CB & C(A - BC) & -CB\beta & 0 & 0 \\ B & (A - BC) & -B\beta & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & I & 0 & 0 \\ CB & C(A - BC) & -CB\beta & 0 & I \end{bmatrix} \bar{y}_{t-1} + \begin{bmatrix} (I - CB)\alpha \\ -B\alpha \\ 0 \\ 0 \\ (I - CB)\alpha \end{bmatrix} + \begin{bmatrix} \beta \\ 0 \\ I \\ 0 \\ \beta \end{bmatrix} p_t.$$

To achieve this definition, the negative of the vector d^* is inserted into the elements of \bar{y}_0 corresponding to d_0 . Initially, d^* is set equal to the expected production over the two-year period. This is simply the most recent year's production plus the estimate of the next year's production from the supply model in (20) and (21). At time period $t = 10$, the second year's actual production becomes known, although it has not yet been processed. Because new information is now available, d^* is then revised by making an adjustment to the elements of \bar{y}_{10} in order to incorporate the new information concerning production levels. For this example, the desired sales level is simply total production. In general, d^* need not equal production. In cases where undesirably large stocks are left over from earlier years, d^* might exceed production in order to reduce stocks.

Noting that all the matrices in the model are time invariant, define new notation for (34) as

$$(35) \quad \bar{y}_t = \bar{A}\bar{y}_{t-1} + \bar{b} + \bar{C}p_t.$$

The loss function can be written in a single quadratic form with a new penalty matrix, Π_t , given by

$$(36) \quad \Pi_t = \begin{bmatrix} 0 & 0 & -.5\rho I & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 \\ -.5\rho I & 0 & R_t & -R_t & 0 \\ 0 & 0 & -R_t & R_t & 0 \\ 0 & 0 & 0 & 0 & S_t \end{bmatrix},$$

where S_t is a null matrix for $t = 1, 2, \dots, T - 1$, and $S_T = S$ where S is the penalty matrix from

(25). The matrices R_t are identical in all periods except two, the first and the eleventh. R_1 is set equal to the null matrix to allow the optimal control model to select the first period's prices p_1 without any penalty for deviations from the initial price levels p_0 . R_{11} is set to one-tenth its value in other periods to allow for the prices to adjust to the added information concerning the actual production levels. It was decided not to set R_{11} equal to the null matrix, thus forcing a

smoother adjustment to the new information.

The optimal control problem can now be written as

$$(37) \quad \min_{\{p\}} \mathcal{L} = \frac{1}{2} \sum_{t=1}^T \bar{y}_t' \Pi_t \bar{y}_t,$$

subject to

$$(38) \quad \bar{y}_t = \bar{A}\bar{y}_{t-1} + \bar{b} + \bar{C}p_t,$$

$$(39) \quad \sum_{t=1}^T q_t \leq s + k.$$

The problem has been transformed into the well-known linear-quadratic deterministic optimal control problem. Given estimates of \bar{A} , \bar{b} , and \bar{C} from the demand system, and a set of penalty matrices, Π_t , the problem given by (37) through (39) can be solved by forming a Lagrangian, taking the derivatives with respect to \bar{y}_t , p_t , and the Lagrange multipliers, and setting them equal to zero. The resulting first-order conditions can be solved to yield a set of Riccati equations which allow for a recursive solution for the parameters of the optimal feedback rule. See Chow for further details. Skipping the intermediary algebra, the feedback rule for choosing the optimal policy instruments, \bar{p}_t , is given by the following equations:

$$(40) \quad \bar{p}_t = G_t \bar{y}_{t-1} + g_t,$$

$$(41) \quad G_t = -(\bar{C}'H_t\bar{C})^{-1}\bar{C}'H_t\bar{A},$$

$$(42) \quad g_t = -(\bar{C}'H_t\bar{C})^{-1}\bar{C}'(H_t\bar{b} - h_t),$$

$$(43) \quad H_{t-1} = \Pi_{t-1} + \bar{A}'H_t(\bar{A} + \bar{C}G_t),$$

$$(44) \quad h_{t-1} = (\bar{A} + \bar{C}G_t)'(h_t - H_t\bar{b}),$$

$$(45) \quad H_T = \Pi_T, \text{ and}$$

$$(46) \quad h_T = 0,$$

where the bars on \bar{A} and \bar{C} and the subscript on H_t distinguish them from the A , C , and H matrices used in the state-space model. Equations (41) through (46) are solved recursively for a set of G_t and g_t , which then allow the optimal price vector for each period to be calculated after the past period's sales have been observed. The feasibility constraints in (39) can be ignored in the solution as they are nonbinding in all time periods.

For the inventory control model, the submatrices in Π_t are set to adjust for the relative scales of the three terms in the objective function: revenue terms are on the order of 10^3 . The selections are $R_t = \text{diag. } (50000, 50000, 50000, 50000, 50000)$, with the adjustments discussed above for the time periods $t = 1$ and $t = 11$, and $S_T = \text{diag. } (.25, .25, .25, .5, .5)$. These values were chosen so that variations in the variables consistent with historical values would not overwhelm, or be overwhelmed by, the revenue terms. In particular, the last two terms in S_T were set to twice the level of the first three because the two corresponding size classes (jumbo and colossal) have production levels significantly lower than the three other size classes. Therefore, the same absolute difference in cases represents a larger percentage difference and deserves to be treated as a larger loss (i.e., smaller misses from the target are larger in a relative sense). For the submatrices in Π_t relating to revenue, the discount parameter is set to $\rho = .988$ as specified above.

Results of the Model Solution

The results of the optimal control model solution showed that, while the model is just an approximation of actual industry behavior, the technique can produce useful policy implications. It would also be easy for an industry to

employ such a method and adapt it to their objectives.

The model took the alternate bearing phenomenon into account by choosing cross-year inventory levels that ranged from one quarter of one month to two months worth of sales for the five size classes. The cross-year inventory levels chosen differed significantly from those that occurred, but the comparison is confused by the large carry-in stocks. These stocks are not factored into the sales targets (although they could be), entering only through the feasibility constraint.

When the information on the actual production levels for the second year entered the model, it adjusted quickly. Over the two-year period, the actual production levels were higher than the forecast. Upon receiving this "news," the prices of all five size classes dropped to allow for increased sales. Prices remained at lower levels until the end of the control period, allowing the model to achieve total sales within 2% to 4% of the desired levels for all the size classes. The values for the differences between the sales and production for the two-year period for the actual industry and for the model are given in table 3. A positive number indicates that carry-in stocks were reduced, and all positive numbers are within the feasible region (the feasibility constraints are all nonbinding). Again, the large positive numbers for the actual industry in all the size classes except for the colossal indicate that the industry is reducing its "permanent" inventory levels. The failure to reduce the inventory levels of the colossal size is important because considerable stocks exist in this size class.

Another positive sign of the model's performance was that the sales levels followed a cyclical pattern, peaking in the months when the seasonal demand for olives is highest. This implies that the state-space part of the demand model is allowing the seasonal variations in demand to be tracked with reasonable accuracy. The cycle embodied by the state-space model allows for a smoother transition to these seasonal changes than the inclusion of dummy variables in the demand system.

The price levels set by the model diverged from the actual levels that occurred. The prices set by the model for the large size class were higher than the actual ones; for the medium, jumbo, and colossal sizes the prices set were lower, and for the small size class the prices set by the model were approximately the same as actually occurred. This feature of the solution is the result of the sales constraint imposed through the pen-

Table 3. Sales Minus Production for 1985–86

ality matrix S . Examination of industry statistics shows that, for the past five years, inventory levels have been increasing steadily and now equal one-half of an average year's production. The control model did not allow the industry to increase stocks greatly, as it has often been doing. The results of the control model suggest that the industry must adjust its pricing structure to avoid excessive inventory levels. The model selected prices which vary more by size class than the actual prices, keeping prices high for the size classes with strong demand while reducing other prices to avoid increasing inventories further. For example, for the highest volume size class, large, the control model suggests about a 12% price increase; while, for the two lowest volume classes, jumbo and colossal, the control model suggests price cuts of approximately 38% and 57%, respectively. The ratios of the means of the proposed prices to the means of the actual prices are presented in table 4. Recalling the numbers in table 3 for sales minus production, the huge difference between the proposed and the actual prices for the colossal size class suggest that the industry is building up large "permanent" inventories of the colossal size class. To stop this practice, the model suggest a price cut of over 50%.

Finally, the results of the optimal control model are not sensitive to the values of the penalty matrices R and S . Experimentation with a range of values within the same order of magnitude showed no significant sensitivity of the price or sales levels to the exact values of R and S . This suggests that the answers produced by the control model are a result of the supply and demand models and the general form of the criterion function rather than being forced onto some "desired" path by the penalty matrices.

Conclusions

This paper has shown that state-space models can be used to predict the cyclical patterns present in the supply and demand functions of many agricultural products. State-space models are well-suited to such problems because they can model both the alternate bearing phenomenon on the supply side and any seasonal fluctuations in demand. Such techniques may prove useful to a number of agricultural industries, as many tree crops exhibit an alternate bearing pattern in their production of fruit or nuts. An augmentation of the state-space model which allows it to be analyzed in the well-known linear-quadratic control framework while properly preserving the dynamics of the system was developed. This allows the state-space models to be used in control problems with known analytical solutions, avoiding the need for complex iterative algorithms. As an example, it was shown that state-space models can be applied to the problem of selecting cross-year inventory levels for agricultural crops with alternative bearing patterns.

In the applications presented here, policy conclusions were drawn related to the industry's pricing policies. It appears that fairly large changes in both relative and absolute prices are needed if the industry wants to avoid building up a sizable permanent inventory. Such a permanent carry-over of stocks is becoming a feature of the industry. Finally, although the model was solved as a closed-loop control problem, over the twenty-four months of the control simulation there were no errors to feed back into the model. If such a model were actually employed, the results should improve since any exogenous shocks could be incorporated into the solutions.

Perennial Crop Supply Response: A Kalman Filter Approach

Keith C. Knapp and Kazim Konyar

A state-space model for perennial crop supply response is developed. New plantings and removals depend on the existing age structure of the crop and expected values for future prices and other exogenous variables. Acreage in individual age categories evolves depending upon existing acreage, new plantings, and removals. The Kalman filter and an iterative parameter search provide maximum-likelihood estimates of the unknown parameters and age group acreages from observed data on total acreage and production. An empirical application for alfalfa shows that existing acreage has differential impacts on new plantings and removals depending upon age.

Key words: Kalman filter, perennial crops, state space models, supply.

A significant literature has developed on the estimation of perennial crop supply response. A number of studies are based on single-equation regression models for either aggregate output, aggregate acreage, or changes in these variables. Akiyama and Trivedi provide a review. This approach is limited because decisions on new plantings and removals depend on existing acreage in the various age categories, as well as existing total acreage and expectations about future prices, yields, and other variables. In addition, the structural models used to derive the reduced-form estimating equations typically assume desired levels of acreage or output as a function of prices and a partial adjustment or stock adjustment model to determine investment or changes in acreage or output. With stable prices and other exogenous variables and an adjustment coefficient between zero and one, this implies convergence to a steady-state or long-run equilibrium, which need not be the case for perennial crops (Knapp).

Several studies have provided separate estimates of new planting and removal equations which account, at least in part, for age distribution effects. These include French and Bressler for lemons; Arak for coffee; Alston, Free-

bairn, and Quilkey for oranges; French, King, and Minami for cling peaches; Akiyama and Trivedi for tea; and Hartley, Nerlove, and Peters for rubber. However, these studies utilize data on new plantings, removals, and age distribution which are not generally available for most crops in most regions. Bellman and Hartley propose an approach utilizing "neoclassical econometrics," but no empirical estimates are given. Knapp investigates a normative model for alfalfa.

For many perennial crops there is limited or no data on new plantings area, removals, and area in individual age groups. Thus, the problem remains of econometrically estimating perennial crop supply response with aggregate acreage and production data while still accounting for age-group dynamics in a theoretically correct manner. This paper proposes the use of state-space models and the Kalman filter to solve this problem. State-space models have system dynamics with (possibly) unobservable state variables and measurement equations relating the state variables to observable variables. The Kalman filter generates optimal estimates of the state variables and their variance-covariance matrix. The perennial crop problem is reformulated here as a state-space model, and the Kalman filter is used in conjunction with an iterative search to generate parameter estimates as well as estimates of new plantings, removals, and existing acreage by age group. An empirical application to California alfalfa production is given.

Keith C. Knapp is an associate professor of resource economics, University of California, Riverside. Kazim Konyar is an agricultural economist, U.S. Department of Agriculture.

Phyllis Nash provided assistance with the graphics. The authors are also grateful to two anonymous referees for comments motivating an expansion of the original analysis.

Theory

An individual producer is considered. The producer makes new plantings and removes existing acreage to maximize profits over an infinite horizon. The model, derived from Knapp, is also a simplified version of the model in Bellman and Hartley. The following variables are defined: A_{1t} is new plantings, beginning of year t ; A_{it} is existing area of the perennial crop at the beginning of year t which will be in the i th year of production during year t if produced, $i = 2, \dots, n$; and R_{it} is the area of the perennial crop in the i th year of growth which is removed from production at the beginning of year t , $i = 2, \dots, n$. Here n is the maximum number of age categories considered. A_{1t} and R_{it} are control variables, while A_{it} , $i = 2, \dots, n$ are the state variables.

The age group dynamics are given by

$$(1) \quad A_{i,t+1} = A_{i-1,t} - R_{i-1,t},$$

where $i = 2, \dots, n$ and $R_{1t} = 0$. Profits from the perennial crop depend on the cost of new plantings and removals, annual production costs, the opportunity cost of land planted to the perennial crop, and revenue received. Present value of profits is given by

$$(2) \quad \sum_{t=1}^{\infty} \alpha^t \pi(A_{1t}, \dots, A_{nt}, R_{1t}, \dots, R_{nt}; P_t),$$

where α is the discount factor, P_t is a vector of prices and other exogenous variables, and π denotes annual profits as a function of acreage, removals, and prices. The producer's problem is to maximize (2) subject to (1) and nonnegativity conditions on the variables.

This is a dynamic programming problem. Under appropriate assumptions about π , an optimal value function J_t exists for each year which gives the present value of profits in future years under optimal operation:

$$(3) \quad J_t(A_{2t}, \dots, A_{nt}; P_t, \dots, P_{\infty}) \\ = \sum_{s=t}^{\infty} \alpha^s \pi(A_{1s}^*, \dots, A_{ns}^*, R_{1s}^*, \dots, R_{ns}^*; P_s),$$

where A_{it}^* and R_{it}^* denote optimal levels of the state and control variables; J_t is a function of the state variables and depends parametrically on prices and other exogenous variables.

Optimal values for the decision variables in each year are chosen to maximize

$$(4) \quad \pi(A_{1t}, \dots, A_{nt}, R_{1t}, \dots, R_{nt}; P_t) \\ + \alpha J_{t+1}(A_{2,t+1}, \dots, A_{n,t+1}; P_{t+1}, \dots, P_{\infty})$$

subject to (1) and the nonnegativity conditions. Optimal decision rules can then be written as

$$(5) \quad A_{1t}^* = f_1(A_{2t}, \dots, A_{nt}; P_t, \dots, P_{\infty})$$

$$(6) \quad R_{it}^* = g_i(A_{2t}, \dots, A_{nt}; P_t, \dots, P_{\infty})$$

for $i = 2, \dots, n$. Thus, the optimal values for A_{1t} and R_{it} depend on existing acreage of the crop in each age group and future prices. A theoretical model for perennial crop supply response is given by (1), (5), and (6) after specification of the appropriate functions.¹

Empirical Model

A linear model is specified for empirical estimation. Observations are assumed to be available for total acreage and production of the perennial crop and various exogenous variables believed to influence crop supply. However, new plantings, removals, and acreage by age category are not directly observable. This is the situation for many perennial crops.

New plantings are given by

$$(7) \quad A_{1t} = \sum_{j=2}^n a_j A_{jt} + \sum_{j=1}^m b_j Z_{jt} + e_{1t}^n,$$

where Z_{jt} are exogenous variables, m is the number of exogenous variables, and e_{1t}^n is a white-noise error term; $Z_t = (Z_{1t}, \dots, Z_{mt})$ includes expected values for future prices and other exogenous variables. Removals are specified as

$$(8) \quad R_{it} = \sum_{j=2}^n c_{ij} A_{jt} + \sum_{j=1}^m d_{ij} Z_{jt} + e_{it}^r,$$

where $i = 2, \dots, n$ and e_{it}^r is a white-noise error term. Total acreage during year t is then

¹ The model in this section of the paper implicitly assumes that future values of prices (and other exogenous variables) are either known with certainty or that the conditions implying certainty equivalence are met. Neither of these assumptions is likely to be completely true in practice. The implication is that the optimal decision rules for new plantings and removals [eqs. (5), (6) in the text] depend parametrically on all moments of the probability distribution for future prices and other exogenous variables and not just the expected values as implied in the text. In the ensuing empirical analysis, we follow most studies in empirical agricultural supply response analysis and consider only the expected values of price and other exogenous variables, while acknowledging that a more complete empirical analysis would include higher moments as well.

$$(9) \quad A_t = \sum_{i=1}^n (A_{it} - R_{it}) + e_t^a,$$

where e_t^a is again a white-noise error term. Equation (9) assumes that total acreage (A_t) is subject to measurement error. Total production is given by

$$(10) \quad Q_t = \sum_{i=1}^n y_{it}(A_{it} - R_{it}) + e_t^q,$$

where y_{it} is crop yield for age-category i in year t . The y_{it} are assumed to be known coefficients; e_t^q is also a white-noise error term which is independent of e_t^a , e_t^n , and e_{it}^r .

The complete empirical model is equations (1) and (7)–(10). The coefficients to be estimated are a_j , b_j , c_{ij} , d_{ij} , and the covariance matrices for the error term vectors (e_t^a , e_t^q) and (e_t^n , e_{it}^r). Given estimates of these coefficients and the expected values and variance-covariance matrix for A_{io} and R_{io} , then estimates of A_{it} and R_{it} , $t = 1, \dots, T$, can also be constructed. These estimations are carried out by recasting the model in state-space form and using a Kalman filter combined with an iterative search over the parameters. This procedure is described in the next section.

Estimation Procedure

The perennial crop empirical model defined by equations (1) and (7)–(10) is first recast in state-space form. Substituting (1) into (7) and (8) gives

$$(11) \quad A_{it} = \sum_{j=2}^n a_j(A_{j-1,t-1} - R_{j-1,t-1}) + \sum_{j=1}^m b_j Z_{jt} + e_t^n,$$

$$(12) \quad R_{it} = \sum_{j=2}^n c_{ij}(A_{j-1,t-1} - R_{j-1,t-1}) + \sum_{j=1}^m d_{ij} Z_{jt} + e_{it}^r,$$

where $i = 2, \dots, n$. In (11) and (12) the Z_{jt} are exogenous variables with known values; however, the coefficients b_j and d_{ij} are unknown parameters. In the state-space model, b_j and d_{ij} can therefore be treated as state variables with system dynamics given by

$$(13) \quad b_{jt} = b_{j,t-1} \text{ and}$$

$$(14) \quad d_{ijt} = d_{ij,t-1},$$

where $i = 2, \dots, n$ and $j = 1, \dots, m$. Mean

values and variance-covariance matrices for the initial values of b_j and d_{ij} must also be specified.

The state variables for the empirical model in state-space form are A_{it} , $i = 1, \dots, n$; R_{it} , $i = 2, \dots, n$; b_{jt} , $j = 1, \dots, m$; and d_{ijt} , $i = 2, \dots, n$, $j = 1, \dots, m$. The observed variables are A_t and Q_t , $t = 1, \dots, T$. The measurement equations are (9) and (10), while system dynamics are given by equations (11), (1), and (12)–(14). The unknown parameters to be estimated in the state-space model are a_j , c_{ij} , the variance-covariance matrices for the error terms, and the expectations and variance-covariance matrix for the state variables at $t = 0$. Let this set of unknown parameters and initial conditions be denoted U .

With these equations and variable definitions, the model is in state-space form for given values of the parameters and initial conditions in U (Judge et al.). The Kalman filter can then be used to give optimal estimates of the state-space state variables and their variance/covariance matrix for given values in U , as well as the value of the log-likelihood function. Iterations over the values of the parameters and initial conditions in U are then conducted to find maximum-likelihood estimates for all unknown coefficients. Details for the particular empirical application considered here are available from the authors upon request.

Data

The model is applied to alfalfa production in California. Alfalfa is typically planted for three to four years and then removed from production. Therefore, the empirical model is estimated with four age groups. The estimations are carried out using data from 1945–85. Except where noted, data sources are described in Konyar and Knapp.

Age-specific yields are required to specify the quantity measurement equation (10). Based on Knapp, relative yields are defined by $y_{it} = a_i y_{2t}$, $i = 1, \dots, n$ and $(a_1, \dots, a_n) = (.66, 1., .92, .84)$. There has been a significant upward trend in California alfalfa yields. A time-series regression for the period under consideration gives

$$\bar{y}_t = 4.31 + .054 * t \quad R^2 = .92, \\ (72.76) \quad (21.12)$$

where \bar{y}_t denotes the trend in average yield (tons/acre) and t -statistics are given in parentheses. The average expected yield in each period is as-

summed to equal the trend of the average yield in that period:

$$\sum_{i=1}^n y_{it}/n = \bar{y}_t,$$

which implicitly defines y_{2t} and hence y_{it} for each period t using the definitions and coefficients described above.

From the theoretical model, new plantings and removals depend on existing acreage and expected profitability of growing alfalfa. Expected profitability depends in turn on expected revenue from alfalfa minus production costs and the opportunity cost of using land for alfalfa production. Prices received for competing crops are used here as a surrogate for land opportunity costs. The new plantings and removal functions are therefore specified as

$$(15) \quad A_{it} = \sum_{j=2}^4 a_j (A_{j-1,t-1} - R_{j-1,t-1}) + b_1 + b_2 TRALF_t^* + b_3 PCINDX_t^* + b_4 CCINDX_t^* + e_t^n \text{ and}$$

$$(16) \quad R_{it} = \sum_{j=2}^4 c_{ij} (A_{j-1,t-1} - R_{j-1,t-1}) + d_{i1} + d_{i2} TRALF_t^* + PCINDX_t^* + d_{i4} CCINDX_t^* + e_t^r,$$

where $TRALF_t^*$ is the expected total revenue from alfalfa production (\$/acre), $PCINDX_t^*$ is the expected value for a production cost index, and $CCINDX_t^*$ is the expected value of an index for the prices of competing crops; $TRALF_t^*$ is further defined as the expected price of alfalfa times expected yield, where expected yield is calculated from the above regression of alfalfa yields on time.

The main empirical results presented in the paper assume naive expectations for prices and production costs. Thus, expected alfalfa prices, $PCINDX_t^*$ and $CCINDX_t^*$ just equal their actual values lagged one year. $PCINDX$ (1977 = 100) is based on U.S. Department of Agriculture (USDA) statistics, while $CCINDX$ (1975 = 1.0) is constructed by calculating a weighted average of prices received for eight California field crops and then using 1975 as the base year. A separate section also considers quasi-rational expectations in the sense of Nerlove, Grether, and Carvalho. In this case, expectations are calculated from ARIMA models for the individual time series.

Finally, the error terms in the measurement and systems equations are assumed to be mutually independent. This implies that only the variances of the individual error terms need to be estimated; the covariances are assumed to be zero.

Empirical Results

Table 1 gives the estimated coefficients for the new plantings equation (15). The negative age-group coefficients in the new plantings equation imply that, everything else equal, an increase in existing acreage results in a decrease in new plantings. This is consistent with a priori expectations based on theoretical considerations.² Also, both the magnitude (absolute value) and statistical significance of the age-group coefficients a_j decrease as j increases. Thus, existing acreage in older age categories has less influence on new plantings than does existing acreage in younger age categories.

The coefficient for $TRALF_t^*$ is positive, while the coefficients for $PCINDX_t^*$ and $CCINDX_t^*$ are negative. Thus, new plantings increase as expected gross revenues from alfalfa production

increase, as expected production costs decrease, or as the expected returns from other crops decrease. These results are also consistent with a priori considerations. The R^2 value for the new plantings equation is somewhat low (.293) suggesting that other functional forms or explanatory variables could be tried in future work. The Durbin-Watson statistic does not suggest the presence of serially correlated error terms.

Coefficient values for the removal equations (16) are also given in table 1. The age-group coefficients c_{ij} are all positive for $i = j$ and significantly larger in absolute value than the coefficients c_{ij} , $i \neq j$, by an order of magnitude or more. These results are consistent with biological considerations in growing perennial crops. In general, some fraction of existing acreage is removed each year because of poor stands, disease, or pest damage. Also, the length of time alfalfa stands are kept in the ground varies regionally due to climatic differences. For example, alfalfa stands may typically last three years in the Imperial Valley in California but four years in the Central Valley. Thus, holding prices constant, removals in age group j will be positively

² Imagine the system is initially at a steady state. If $a_j > 0$, then an increase in existing acreage over the steady-state level would increase new plantings and total acreage would continually increase over time. If $a_j < 0$, then an increase in existing acreage decreases new plantings and the system can return to a steady state.

related to, and most strongly affected by, existing acreage in the same age group.

The results in table 1 also show that removals decrease as expected alfalfa gross revenues increase and increase as expected production costs and returns from competing crops increase. All coefficient values in the removal equations are significant at the 1% level, the R^2 values are quite high, and the Durbin-Watson statistics are not suggestive of serial correlation in the error terms.

Figure 1 shows estimated new plantings and removals of age categories 2 and 3 from the KF smoother recursions. Estimated new plantings exhibit considerable variability. Removals of second-year acreage are almost constant; removals of third-year acreage exhibit somewhat greater variability. Estimated values for year 4 removals (not reported) are somewhat lower on average than year 3 removals and exhibit a slightly lower range of variation. Time-series plots for acreage in age categories 2–4 (also not reported) are qualitatively similar to the time-series plot for new plantings in figure 1 after a suitable number of lags. Because removals are positive, acreage in each age category is somewhat less than acreage in the previous age category, and this also tends to dampen the observed variability over time.

The observed variables in this analysis (other than exogenous variables) are assumed to be alfalfa production and total acreage in California.

Fitted values for A_{it} and R_{it} are calculated from equations (1) and (15)–(16) with the error terms set to zero and where estimated values from the Kalman filter smoother recursions are used for the unobserved acreage and removal variables on the right-hand side of these equations. The fitted values for A_{it} and R_{it} are used to calculate fitted production and total acreage, and these are plotted in figure 2 along with actual values. This procedure is analogous to computing fitted values for ordinary least squares (OLS) regressions.

Fitted production tracks actual alfalfa production quite well, with significant deviations in only a few years. The model tracks total alfalfa acreage somewhat less well. Although the fitted results follow the overall observed trends in actual areas, there are significant deviations in several years. These results correspond with the estimated standard deviations of the error terms for the measurement equations. For production, the estimated standard deviation of e_t^q is 9.8×10^{-6} tons and the standard deviation of e_t^a is 4×10^4 acres. (Note that both standard deviations are relatively low in comparison to an average total alfalfa area of 1.1×10^6 acres and yield of 5.4 tons/acre over the period 1945–85.)

Long-run equilibrium or steady state occurs for values of A_{it} and R_{it} which, once achieved, are maintained indefinitely for given values of the exogenous variables. Long-run equilibrium

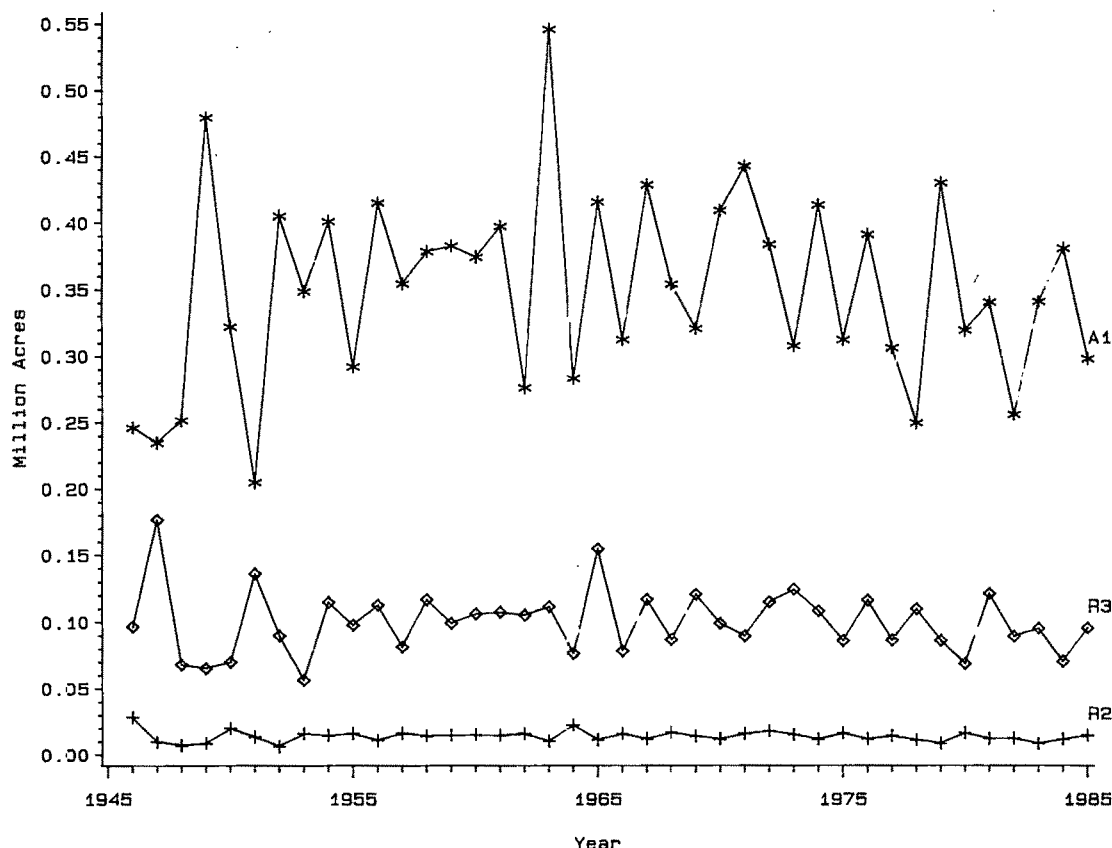

Figure 1. Time-series plots for estimated new alfalfa plantings in California (A1), and removals in age-categories 2 (R2) and 3 (R3)

values for A_{it} and R_{it} can be calculated from equations (1) and (15)–(16) after dropping the time indices. This constitutes a system of seven equations in seven variables (noting that $R_1 = 0$), which was solved using *Mathematica* (Wolfram) to obtain steady-state values of A_i and R_i as functions of the exogenous variables. Total alfalfa acreage in long-run equilibrium is then given by

$$(17) \quad A^* = 1.32 + 1.17 \times 10^{-3} \text{TRALF}^* - 1.99 \times 10^{-3} \text{PCINDX}^* - .512 \text{CCINDX}^*$$

for the estimated parameter values in table 1. Using 1983–85 average values for the exogenous variables, long-run equilibrium total acreage is estimated as 1.08 million acres which is quite close to the average of 1.1 million acres over the period 1945–85.

Price elasticities are reported in table 2 for quantity supplied in the California alfalfa market. Short-run (1 year) elasticities are calculated from equation (9) after substituting in the esti-

mated equations (15)–(16), dropping the error term, and using 1983–85 average estimated values for A_{it} from the KF smoother recursions. Long-run elasticities are calculated using equation (17). All calculations are based on 1983–85 average values for prices, yields, and acreage. The results suggest that alfalfa supply is inelastic in both the short and long run.

Forecasted alfalfa area was calculated under alternate initial conditions assuming 1983–85 average values for yield and the exogenous variables. One simulation uses estimated values from the KF smoother recursions to specify initial (1985) values for A_{it} and R_{it} . Since 1985, total alfalfa acreage is quite close to the long-run equilibrium acreage calculated earlier, the calculated time path is relatively constant; there are some minor fluctuations in the early years because individual age groups are not at long-run equilibrium levels. To further explore the dynamic behavior of the estimated system, a lower initial total acreage equal to $.4 \times 10^6$ acres and a higher initial total acreage of 2×10^6 acres

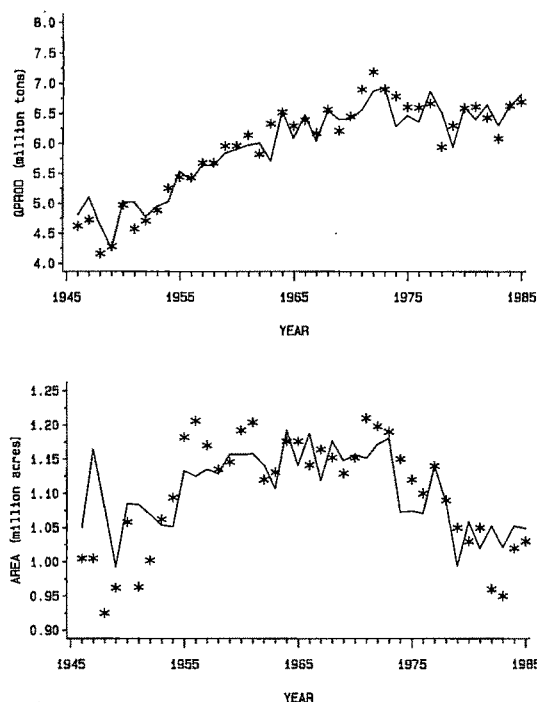

Figure 2. Actual (*) and fitted (—) production (a) and acreage (b) for the California alfalfa market

are also considered. In both cases the system converges to a long-run equilibrium in approximately four to five years after some initial fluctuations about that level.

Quasi-Rational Expectations

This section considers quasi-rational expectations in the sense of Nerlove, Grether, and Carvalho. The authors show (pp. 302–8) that under the rational expectations hypothesis, price expectations can be represented as an ARIMA model with coefficients depending on the coefficients in the structural model. Quasi-rational expectations then consist of estimating ARIMA

Table 2. Price-Elasticities of California Alfalfa Quantity Supplied (naive expectations)

models for the price expectations but ignoring the cross-equation parameter restrictions and then using predicted values from the ARIMA models for expected price.

Quasi-rational expectations are implemented in this study as follows. First, standard time-series methods (Shumway) are used to identify the following models:

log alfalfa price:	ARIMA (2, 2, 0)
log PCINDX:	ARIMA (0, 2, 2)
log CCINDX:	ARIMA (0, 1, 1)

where the entire data series 1945–85 is used in the identification process. Second, for each year t from 1955 to 1985, the above ARIMA models are estimated using data from 1945 to year $t - 1$, and forecasts generated for years s , $s = t, \dots, t + 3$. The four-year average is then used to specify $TRALF_t^*$, $PCINDX_t^*$, and $CCINDX_t^*$ in equations (15) and (16). Finally, the unknown parameters and acreage and removal variables are estimated as before, except that the estimation is carried out for the years 1955–85 instead of 1945–85 under naive expectations.

Table 3 gives the estimated coefficients for the new plantings and removal equations under quasi-rational expectations. The signs of the estimated coefficients in table 3 are roughly comparable to those under naive expectations (table 1). Exceptions are the signs for some age group coefficients in the removal equations and the signs for $CCINDX^*$ in the new plantings equation and the removal equations for age groups 2 and 3. In particular, an increase in the price of competing crops under the quasi-rational expectations hypothesis implies an increase in new plantings area in contrast to what might be expected a priori. The estimated coefficients under quasi-rational expectations are roughly comparable in order of magnitude to the estimated coefficients under naive expectations. Other than that, the most notable differences are higher age-group coefficients and lower $TRALF^*$ coefficients (in absolute value) under quasi-rational expectations.

Table 4 gives the price elasticities for California alfalfa supply under quasi-rational expectations. Here the own-price elasticity is implausibly low (3% in both the short and long run). The production cost elasticities are quite close to those under naive expectations. The elasticity of competing crop prices is positive in contrast to both the results under naive expectations and a priori reasoning. Long-run equilibrium acreage is calculated as 1.04 million acres, which is slightly lower than estimated under naive ex-

pectations. Forecasted acreage was also estimated for the period 1986–2025 under the same initial conditions and values as before. As with naive expectations, total alfalfa acreage under quasi-rational expectations exhibits a damped cycle with eventual convergence to a long-run equilibrium. However, convergence to long-run equilibrium takes noticeably longer (10–20 years) with supply response estimated under quasi-rational expectations, even assuming constant expected prices and costs during the forecast period.

Conclusions

Previous econometric studies of perennial crop supply response have been based on OLS estimates of single-equation, reduced-form regressions for aggregate output or acreage, or OLS

estimates of individual new planting/removal equations. The first approach does not adequately account for age-distribution impacts on new plantings and removals, while the second approach requires detailed data which are not always available. A state-space approach using the Kalman filter is proposed here. The structural model includes age-distribution effects and separate new planting, removal, and age-group dynamics. Both parameter and age-group acreage estimates are obtained from data on total acreage, production, and prices.

The model is applied to alfalfa production in California. Under naive price and cost expectations, the estimated model provides a reasonable fit to the data. The correct signs were obtained and the price coefficients are generally statistically significant. Estimated long-run equilibrium is close to average acreage over the sample period. The results suggest that alfalfa supply is inelastic in both the short- and long-run. Total acreage converges to long-run equilibrium under constant prices, but with some overshooting. The model was also estimated assuming quasi-rational expectations. The estimated coefficients are generally comparable in sign and order of magnitude to those under naive expectations. However, the own-price supply elasticity is much less than that under naive expectations, and the elasticity with respect to competing crop prices is positive. In general, the results here under naive expectations seem

more consistent with a priori considerations than those under quasi-rational expectations.

Age-structured models arise naturally in many areas of natural resource economics (Wilén). Examples include fisheries, forests, and wildlife herds. In many instances births and/or deaths may depend on the age-structure of the population; thus, accounting for age-structure is necessary for obtaining accurate theoretical and empirical models. Age-structured models also arise in other areas of economics, such as capital theory. In a given industry, for example, existing capital may be quite heterogeneous with respect to age. Investment in new equipment therefore depends, in part, on the age-distribution of the existing capital stock. Economic models which explicitly account for the age distribution of physical and biological capital stocks are relatively scarce. This is due in part to difficulties in analyzing such models theoretically (e.g., Cushing) and in part to difficulties in obtaining age-specific data to conduct empirical analysis. Thus, although the focus of this paper is perennial crops, the method can also be applied to estimate age-structured models in other areas of economics when only age-aggregated data is available.³ Current limitations on the use of this method include lack of generally applicable algorithms for state estimation in nonlinear models and parameter estimation in both linear and nonlinear models.

³ Dixon and Howitt (1979, 1980) use a Kalman filter to update estimated volumes and basal areas by age class in a normative study of forestry management. However, they assume that each of these variables is being sampled in each period. This contrasts with the approach here where there is assumed to be no age-specific data on an annual basis and where annual production and acreage data is used to infer age-specific data.

Measuring the Potential Contribution of Plant Breeding to Crop Yields: Flue-Cured Tobacco, 1954–87

Bruce A. Babcock and William E. Foster

Measurements are made of plant breeders' success in increasing potential flue-cured tobacco yields from 1954 to 1987 in North Carolina. Nongenetic sources of yield increases are measured by the yield levels of a standard variety. New genetic material accounted for between 20% and 35% of yield increases on research station plots in the three tobacco-growing regions. Recent genetic contributions have been small. The slowdown is not attributable to a federal tobacco policy shift in 1965 that slowed the growth in grower yields. There is also no evidence that tobacco breeders increased their output in response to the Plant Variety Protection Act of 1970.

Key words: plant breeding, Plant Variety Protection Act, technical change, tobacco.

This paper measures the potential contribution of new genetic material to changes in the per-acre yields of North Carolina flue-cured tobacco between 1954 and 1987. The methodology is generalizable to crops where research station data exist regarding the cultivation of new plant varieties. For agricultural commodities, genetic sources of technical advance occur as new varieties, or cultivars, are produced by private and public plant breeders. Nongenetic sources of technical advance include new production or cultural practices, such as mechanization, fertilization, pest control, and irrigation.

Yields of new tobacco varieties, obtained from university research station data, are used to construct objective measures of tobacco yield increases due to plant-breeding activities. One important issue motivating this analysis is the contribution of research to observed yields of commercial tobacco farms. Therefore, a critical aspect in measuring genetic contribution is the choice of a research-station yield measure that is realistic in terms of grower behavior. For many crops the highest yielding varieties may not be adopted by growers because of the importance

of quality attributes. This is the case with tobacco because of a negative relationship between yields and beneficial leaf chemistry characteristics. Accordingly, this study bases its measure of genetic contribution on the yield levels of varieties that would maximize grower returns, in contrast to basing the contribution on average yield levels of new varieties, or on maximum yields of new varieties.

The use of research station data limits our ability to understand the ultimate effects of new plant varieties. The foremost limitation is that the adoption decision of farmers cannot be considered. Thus, measures of technical change from research station data can, at best, be interpreted as potential technical change. In addition, because the data are not generated in response to the same economic incentives faced by growers, the response of grower yields to changes in input use cannot be measured.

These limitations, however, are balanced by two benefits. First, because this study offers measures of genetic contribution that are independent of farmer adoption rates, the success of research and development in providing potential technical advances can be tested. This is in contrast to those measures derived from rates of cultivation of hybrid varieties (e.g., Heady and Auer, Guise). In addition, simultaneity, caused by the endogeneity of adoption rates, is avoided.

Besides the general question of measuring genetic and nongenetic contributions to tobacco yields, this paper addresses three specific is-

Bruce A. Babcock is an assistant professor, Department of Economics, Iowa State University. This research was completed while he was an assistant professor at North Carolina State University. William E. Foster is an assistant professor, Department of Agricultural and Resource Economics, North Carolina State University. Senior authorship is not assigned.

The authors thank three anonymous *Journal* referees for their helpful comments.

sues. First, by taking advantage of data from several research stations, the analysis can test how contributions of new technology differ across geographic regions. Previous studies of technical change on corn (Offut, Garcia, and Pinar) and wheat (Feyerherm, Paulsen, and Sebaugh) indicate that regional differences can be significant.

Second, the analysis allows a test of the degree to which research and development of new tobacco varieties was influenced by a significant change in economic incentives facing tobacco growers brought about by a change in federal tobacco policy in 1965. Prior to the policy change, supply was restricted through acreage controls; after the change, supply was restricted by marketing quotas (Grise and Griffin). This change in grower incentives altered actual grower yields (Foster and Babcock). Induced innovation theory (e.g., Binswanger and Ruttan) suggests that technical change is influenced by economic variables at the farmer level, but the relative importance to research of variations in farmer incentives is in question.

Third, the analysis allows a test of the influence on new variety yields resulting from a change in direct incentives facing plant breeders brought about by the Plant Variety Protection Act of 1970 (PVPA). The PVPA increased the ability of plant breeders to appropriate the social gains from new varieties, thus increasing the incentives for breeders, especially private firms, to invest in research and development (Perrin and Foster). PVPA effects on private versus public breeding efforts are difficult to distinguish, but in this analysis the distinction is of limited importance because new varieties typically result from private effort.¹

Modeling Technological Contributions to Yield

The use of different amounts and types of production inputs and new production technologies, and the development of new varieties have both contributed to increased yield levels over time. Disaggregating the contribution of genetic

improvements to yields requires observations of the effects of changing production practices on a standard crop variety.² Yields of standard varieties will change from year to year in response to exogenous shocks, (e.g., weather-related variables), and in response to changes in production practices. The yield of new varieties will change in response to the same exogenous shocks and changes in production practices, as well as to changes in genetic makeup.

Generally, one can represent the yield of the standard variety (Y_s) and new variety (Y_n) as $Y_i = Y_i(t, W)$ ($i = s, n$). The time index t represents the systematic influence on yield of technical innovations, both genetic and nongenetic, and changes in W represent all other exogenous influences on yields. Genetic changes do not affect the yield of the standard variety; therefore, the influence of nongenetic technical change on standard variety yields may be represented by $\partial Y_s / \partial t$. Estimates of $\partial Y_s / \partial t$ also represent the total contributions of nongenetic innovations to increased yields of new varieties. Therefore, the contribution of genetic innovations to increased yields can be obtained by subtracting the nongenetic contribution to the standard variety from the total contribution of technical change to new varieties.³

Regional differences may affect the potential contribution of both nongenetic and genetic technical change to commodity yields. Region-specific production practices reflect differing climatic and soil conditions. Official variety tests conducted at North Carolina tobacco research stations explicitly recognize these differences. While the same varieties are tested across regions, the production techniques used at the research stations are chosen to approximate the respective regions' standard or prevailing practices. In addition, the genetic makeup of some new varieties may be better suited for one geographic area than another. Varietal selection for drought resistance, for example, is likely to increase expected yield levels in drought prone re-

² The term "standard variety" denotes a cultivar that is used by crop scientists to gauge the relative contributions of new tested cultivars over a period of time.

³ There are two components to genetic contribution to increased yields. First, holding all other inputs constant; and, second, allowing an interaction between the new genetic input and changes in other inputs. One cannot separate these two components when data reflect an updating of nongenetic techniques. To the grower deciding on a new variety, and hence to the plant breeder, such a distinction may be irrelevant. Indeed, for a given new variety, one component may be negative; but, so long as the other component is positive and sufficiently large, the variety may be adopted. The important question concerns the total yield improvement from the new genetic input relative to the yield under the old genetic input.

¹ As reported by Bowman et al. (table 1, p. 31) of the 105 new cultivars released between 1954 and 1981, 27 were products of public breeding efforts. The most popular varieties with growers were those developed by private firms. For example, in 1989 only one publicly developed flue-cured variety, NC-60, is recorded by county extension agents as being planted in North Carolina, and this variety accounted for only 3% of plantings (Peedin, Smith, and Yelverton, p. 5).

gions more than in regions with regular rainfall or greater reliance on irrigation. Thus, both $\partial Y_s / \partial t$ and $\partial Y_n / \partial t$ may differ by region.

Selecting the New Variety to Represent Genetic Contribution

For most major commodities, private and public research tend to produce several new commercially available varieties in any given year. Table 1 illustrates the average yearly number of new flue-cured tobacco varieties over a number of periods since 1954. What particular new variety, or combination of varieties, should be used to represent genetic contributions to commodity yields? Previous studies, focusing on aggregate state-level measures use average yields of new varieties in a year (e.g., Bowman et al., Heady and Auer). However, other candidates are available. Not all new varieties will be adopted; *ceteris paribus*, lower-yielding varieties will be ignored in favor of the highest yielding, implying that a measure of new genetic material based on average yields of new varieties will tend to underestimate the contribution. In addition, significant research breakthroughs may be overlooked by using the mean yield in measuring the genetic contribution to yields, particularly when many varieties are released simultaneously.

On the other hand, the highest yielding variety is not necessarily the best representative of genetic contribution. Appearance and the ease of product marketing can be important characteristics. In the case of tobacco, a negative relationship exists between alkaloid concentration (a primary determinant of value per pound—increasing alkaloid concentration increases value) and per-acre yields (Matzinger and Mann). If the highest yielding variety is of low quality,

returning little per unit output, then it is unlikely to be adopted. A more economically justifiable measure of genetic contribution is the return-maximizing yield of the new variety.

The profitability of new crop varieties, however, is often difficult to determine. Different varieties may influence grower costs as well as revenues. Gross revenue data based on the government grades of harvested research station tobacco are collected as part of official variety trials; however, data on possible cost differences are not typically available at a research station. If cost differences between varieties at the grower level are minor relative to revenue differences, then the yield associated with the highest per-acre revenue at the research station is the most profitable.⁴

The importance of the measure one chooses as representing the contribution of genetic material to yield growth varies inversely with the correlation between the different measures. If, for example, each year's highest yielding variety for each region is also the most profitable, then for estimation purposes it does not matter what measure one uses. For flue-cured tobacco the correlation coefficients between the yields of the highest yielding varieties and the yields of the varieties with the highest per-acre revenue average 0.98 for North Carolina. The correlation between the average tobacco yields of new cultivars and the yields of the cultivars with the highest per-acre revenue is not much lower at 0.95. This high correlation exists because of the relatively few number of new varieties released

⁴ Although cost differences between varieties at research stations are negligible, cost differences between varieties for growers, who must make the variety-adoption decision, are not necessarily negligible. Different production practices might favor the adoption of different varieties, and vice versa. However, no evidence of this was found, and the assumption appears justifiable.

Table 1. Summary Statistics of North Carolina Official Variety Trials for Flue-Cured Tobacco

Period	Average Number of New Cultivars	Average Yield of New Cultivars ^a	Average Annual Standard Deviation ^b
1954–59	4.8	1908.5	111.9
1960–66	4.3	2443.7	178.1
1967–72	4.0	2512.1	110.7
1973–77	3.0	2878.8	134.2
1978–82	3.0	2945.0	104.0
1983–87	3.2	2840.7	150.4

Source: Calculated from Department of Crop Science, NCSU.

^a The average yield (pounds per acre) is calculated as the average of all yields of new varieties from all the reporting research stations.

^b The average standard deviation is calculated in two steps. First, the standard deviation of yields is calculated from the reported yields in a given year. Second, these standard deviations are averaged over the years in a given period.

each year (table 1). For other major commodities, the correlations are likely lower. For example, between 1971 and 1979, soybean breeders each year produced an average of forty-nine varieties subject to official variety trials (Perrin, Hunnings, and Ihnen, p. 35).

Constructing the Standard Variety

One practical difficulty with using a standard variety is that research station tests on a single standard variety are rarely carried over all years in a sample. A solution is to use overlapping control varieties over a subset of the sample range. Typically, one standard is recorded simultaneously with another. An initial variety is dropped from experimental trials while a second continues, later to be joined by a third, and so on. Using correlations of standard varieties during overlap periods, predictive equations can be estimated to construct a common, synthetic (i.e., hypothetical) standard variety over the entire period.

Flue-Cured Tobacco Data

In 1954, North Carolina State University began its Official Flue-Cured Tobacco Cultivar Variety Trials (NC OVT). An agreement among growers, seed companies, and manufacturers specifies that only varieties tested in the NC OVT shall be released for commercial sale in North Carolina. The data generated by the trials therefore give a comprehensive documentation of the changes in flue-cured tobacco yields since 1954. The trials are conducted at several tobacco research stations representing the major growing "belts" in the state. The data are reported annually prior to the next tobacco planting (Measured Crop Performance: Tobacco).⁵ Monthly

rainfall and irrigation levels at each station are recorded; the weather variables used in this study are the sum of the two. The averages of research station yields within each belt are the basic units of observation.

The standard varieties grown since 1954 are Hicks from 1954 to 1969, NC 95 from 1961 to the present, and NC 2326 from 1964 to the present. To measure the change in yields from non-genetic innovations over the entire sample range requires addressing the change from Hicks to NC 95.⁶ A functional relationship between the two standard varieties was estimated to predict the yield of NC 95 from 1954 to 1960 if it had been grown. Yield observations of NC 95 at each station were regressed on the yield of Hicks and station-specific rainfall variables from 1961 to 1969. ($R^2 = 0.92$.) Yield differences between belts were accounted for by estimating belt-specific intercept terms. Predicted NC 95 values for the three belts from 1954 to 1960 were obtained by applying the estimated coefficients from the OLS regression to observed yields of Hicks and the rainfall variables in those years. These predicted values for NC 95 were added to the series of observed average NC 95 values from 1961 to 1987 to obtain a standardized variety over the entire sample period for each belt.

Numerous advanced breeding lines and commercially available varieties are tested at each research station every year. New varieties are released for commercial sale after being tested for one year as a commercial variety. The potential contribution of new cultivars to commercial yield increases can be estimated by observing trial yields of new varieties. The number of new varieties released ranges from zero in 1963 and 1968 to eleven in 1954. The results presented in this paper are conditional on the new varieties meeting some minimum acceptable quality standard in the 1950s and early 1960s.⁷ Beginning in 1964 these minimum standards became formalized in the Minimum Stan-

⁵ Data from the Border Belt Tobacco Research Station are available every year since 1954. The Eastern Belt is represented by the Upper Coastal Plain Research Station with data from 1954 to 1987, with the exception of 1969; by the Lower Coastal Plain Research Station from 1967 to 1987, with the exception of 1973, 1983, and 1985; and by the Central Crop Research Station from 1956 to 1965, with the exception of 1961. The Old and Middle Belts are represented by the Upper Piedmont Tobacco Research Station from 1954 to 1987, except for 1984 and 1986; and by the Oxford Tobacco Research Station from 1955 to 1987, except for 1962, 1972, 1975, 1979, and 1982. Missing data are the result of complete or major crop failures caused by severe weather or disease infestations. This study combines the Old and Middle Belts into one region that will be called the Old Belt. The practical reason for doing this is the number of missing observations from the research stations in these two belts. A justification for combining the two is that the two belts have similar soil and climate characteristics.

⁶ NC 95 is chosen as the standard variety over NC 2326 because of more years of overlap with observations of Hicks.

⁷ In measuring the contribution of new genetic material to yield increases, three notable varieties were eliminated from the sample. The three are Coker 139 and Coker 140, released in 1954, and Dixie Bright 244, released in 1955. These varieties (especially Coker 139) had significantly higher yields, were significantly easier to cure and handle at harvest time, but they produced significantly lower levels of nicotine and other alkaloids compared to other varieties. Because the tobacco program in the 1950s paid farmers for all production on their acreage allotment (Grise and Griffin), more than 85% of the crop in 1955 and 1956 was planted to these high-yielding varieties (personal communication with Furney Todd, retired professor of agronomy, North Carolina State University). To discourage the production of low quality tobacco, ASCS withdrew price supports for these varieties.

dards Program, and all varieties presently released for commercial sale in North Carolina meet these quality standards.

Results

This section presents estimates of nongenetic and genetic contributions to yield growth. First, yields (lbs./acre) of the standard and new varieties are regressed against weather variables and time using data from three regional research stations. Differential effects of nongenetic technical change across regions are tested. Second, the contribution of genetic change is estimated by regressing the log of the ratio of new varieties to the standard variety against weather variables and time. Tests are made for the differential effects of genetic technical change across regions. Third, the hypothesis that the genetic contribution to yield growth rates of new varieties slowed because of a change in federal tobacco policy is tested. And finally, the hypothesis that the genetic contribution to yield growth rates of new varieties was altered by the Plant Variety Protection Act is tested.

Regression Results

As described in the first section, the contribution of genetics to yield growth is the additional yield growth of newly released varieties over the yield growth of a standard, in this case NC 95. Two possible measures of the breeder-contributed additional yield growth for use in regression analysis are a simple difference between the new variety yields and NC 95, and the log of the ratio of the two yields. The appropriate measure depends on the functional forms explaining the yields of the standard and new varieties. If yields are linear in the included variables with an additive error term, then the yield difference between NC 95 and the new varieties is an appropriate measure of genetic contribution. If the functional forms for the yield equations have a multiplicative error structure, then the log of the ratio is appropriate. A log functional form was considered more appropriate after diagnostic tests revealed the presence of heteroscedasticity when strict linearity was assumed. Results reported here are for the loglinear case, where the log of yields is regressed against weather variables and the log of the time index.⁸

⁸ The quantitative results for the loglinear case (log-yield against log-time) and the semilog case (log-yield against simple time) are similar.

For each of the three regions, the following equations were used to estimate the nongenetic contribution to growth in tobacco yields:

$$Y_{srt} = k_{sr} + f_r(t) + W_{rt}\beta_{sr} + \epsilon_{srt}$$

$$y_{nrt} = k_{nr} + g_r(t) + W_{rt}\beta_{nr} + \epsilon_{nrt}$$

where y_{srt} and y_{nrt} represent annual yields (in log pounds per acre) of the standard (s) and new varieties (n) in region r (r = Eastern, Old, and Border Belts) and year t ; k_{sr} and k_{nr} are constant terms specific to variety and region; $f_r(t)$ and $g_r(t)$ are quadratic functions of time ($t = 1, 2, 3, \dots$); W_{rt} represents a vector of June, July, and August rainfall (in inches); and ϵ_{srt} and ϵ_{nrt} represent possibly contemporaneously correlated errors.

The results are presented in table 2. The set of equations was estimated as seemingly unrelated because the null hypothesis of no contemporaneous correlation between the error terms of the six equations was rejected at the 1% confidence level. All the coefficients on time are positive and significantly different from zero. In addition, seventeen of the eighteen rainfall coefficients are negative.⁹

Testing for Differential Effects of Technical Change

A differential effect of nongenetic technological change across regions was tested by restricting the estimated coefficients relating time to the yields of NC 95 to be the same across the three regions. The null hypothesis that the effects are equal can be rejected at a 1% confidence level with a calculated F -statistic of 5.83 with 2 and 162 degrees of freedom. Thus, the evidence suggests that nongenetic technological progress has had a differential impact on the three growing regions.

Given the log-linear functional forms, the contribution over time of new genetic material can be obtained by regressing the log of the ratio of the yield of new varieties to the yield of NC 95 on the log of time and rainfall.¹⁰ One equation for each of the three growing belts allows

⁹ Rainfall-squared terms were added to the regressions to account for probable positive, but decreasing, returns from rainfall at low levels of rainfall. The contribution of these terms was negligible, perhaps because of irrigation practices at the research stations in drought years.

¹⁰ The hypothesis of an identical response of NC 95 and the new varieties to the rainfall variables within each of the regions was rejected ($F = 3.17$ with 9 and 162 degrees of freedom). Thus, the rainfall variables are included in the genetic contribution regressions.

New variety	7.671 (119.)	0.143 (8.83)	0.00034 (0.28)	-0.0152 (2.91)	-0.00052 (0.10)	0.77
Standard variety	7.713 (129.)	0.105 (7.09)	-0.00210 (1.87)	-0.00641 (1.30)	-0.00703 (1.44)	0.70

^a The dependent variables in the regressions are log yields for the standard variety (NC 95) or the new variety series; *T* is the log of an annual time index that *T* = 1 in 1954; *MAY*, *JUNE*, and *JULY* are inches of rainfall plus inches of applied irrigation water for May, June, and July.

^b The absolute value of the estimated *t*-ratios are given in parentheses.

for differential rates of genetic change across belts. The hypothesis of no contemporaneous correlations among the error terms of the equations was again rejected, and the three equations were run as seemingly unrelated regressions.

Table 3 first reports the regression results assuming regional differences. The estimated annual rate of yield increase from the introduction of new genetic material for a given year, say *t'*, is found by taking the derivative of a genetic contribution equation with respect to time (i.e., $\partial \ln [Y_n/Y_s]/\partial t$) and evaluating at year *t'*. For

example, in the Eastern Belt for 1965, *t'* = 17, and the growth rate equals $\partial \ln [Y_n/Y_s]/\partial t = 0.0556/17 \approx 0.0033$. The estimated average annual rate of yield increase is found by averaging the individual growth rates over the sample period. The resulting rate of yield increases for the period 1954 to 1987 are 0.67% for the Eastern Belt, 0.51% for the Old Belt, and 0.47% for the Border Belt. A test that these growth rates are significantly different across equations can be accomplished by restricting the three time coefficients to be equal. The calculated *F*-sta-

tistic for testing these restrictions is 0.34, with 2 and 81 degrees of freedom. In contrast to non-genetic change, there is no evidence of a differential impact of genetic research effort across the three tobacco growing belts. Table 3 also reports the regression results imposing these restrictions. The average annual rate of yield increase resulting from new genetic material implied by this restricted regression is approximately 0.54%.

The total yield effect from changes in technology is the sum of the genetic and the non-genetic contributions. The average annual rate of increase of NC 95 can be obtained from the regression results in table 2. The estimated annual growth rate for a given year, say t' , is found by $\partial \ln y_t / \partial t$ evaluated at t' . The average growth rate is found by averaging the individual years' growth rates. The yield of NC 95 grew by average annual rates of 1.07% in the Eastern Belt, 2.05% in the Old Belt, and 1.27% in the Border Belt. The percent of average rates of annual yield increases attributable to new genetic material is found by dividing the estimated average growth rate resulting from new varieties by the sum of growth rates from new varieties and nongenetic gains. The results are 34% in the Eastern Belt

(i.e., $.34 \approx .54 / [.54 + 1.07]$), 21% in the Old Belt, and 30% in the Border Belt. The findings here of differential growth rates within a state are similar to those of Offutt, Garcia, and Pinar, who found that growth rates of corn yields differ across crop reporting districts in Illinois.

Figure 1 illustrates how these growth rates affect the yields of the new variety series and NC 95 in the Eastern Belt. The log of the new variety yield series is the broken line in figure 1. The fitted trend line for this series is taken from the coefficients in table 2. The contribution of changes in production practices to the yields of the new varieties in the Eastern Belt (the lower solid line in fig. 1) is found by subtracting the contribution of genetic material. This contribution was calculated from the restricted regression results in table 3. The contribution of genetics is set to zero in 1954.

Testing for a Plant-Breeder Response to Changed Incentives

The decline in yield growth rates of both the standard variety and the new varieties has several explanations. One is that a "natural" slow-

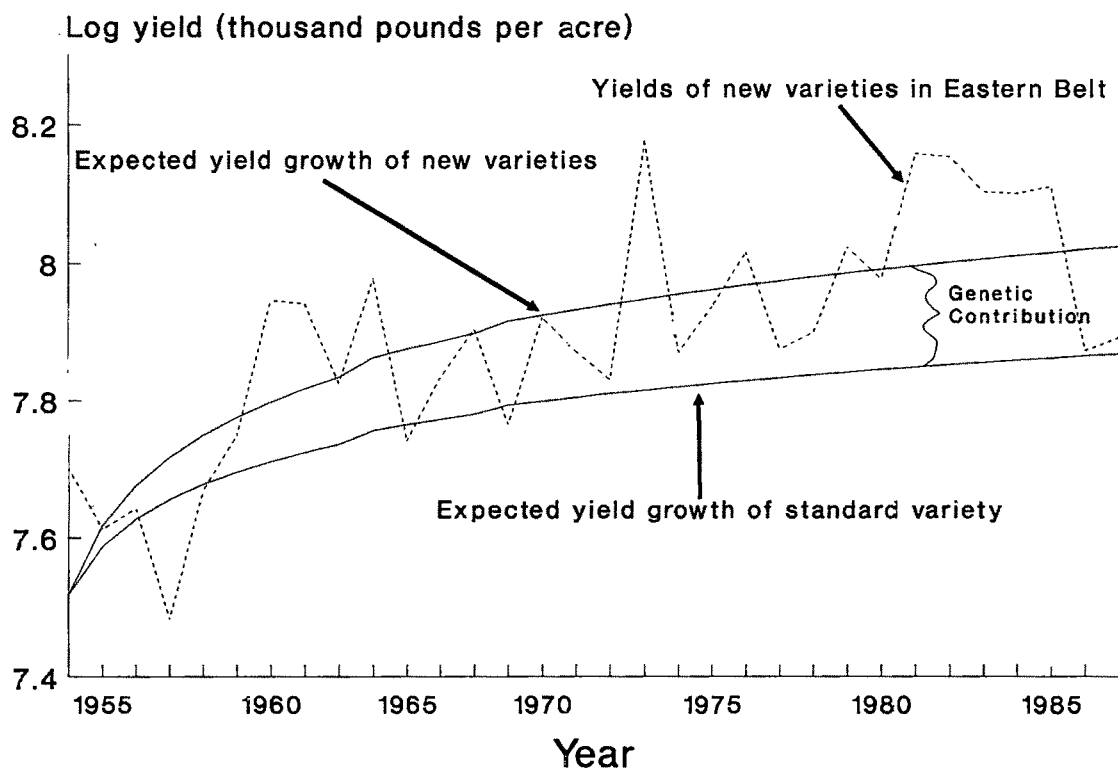

Figure 1. Genetic contribution to yields in the Eastern Belt

down occurred. A slowdown in the growth rate of the yield of NC 95 would appear inevitable given a constant stock of genetic material. A slowdown in the rate of discovery of new genetic material would be expected also once all the possible combinations of existing genetic sources were exhausted.

On the other hand, if plant breeders are responsive to the same economic incentives facing grower clientele groups, then the slowdown might be explained by the major change in flue-cured tobacco policy in 1965. Such a "demand-pull" explanation is consistent with the induced innovation literature. In 1965 acreage allotments were replaced by poundage controls. Foster and Babcock showed that in response to this change in federal policy, expected flue-cured tobacco yields at the county level decreased and the rate of increase of subsequent yields declined. Average county-level tobacco yields and the fitted trend line from their study are shown in figure 2. The average of the three new variety series from the present analysis are also shown in figure 2. A discrete change in the growth rate and/or yield level of new varieties beginning in 1965 would be consistent with the explanation that re-

searchers altered their research goals because of the change in federal tobacco policy.

This hypothesis was tested in the following way. Regime changes for years after 1964 account for possible time lags due to product development.¹¹ Separate tests were performed for shifts in time coefficients and constant terms for periods following each year from 1964 to 1978. For example, to test whether or not a regime change occurred in the development of new varieties six years following the policy change, a test was made for the inclusion of constant and slope dummies that have the value zero prior to 1970.

In the case of an immediate shift in 1965 resultant from the program change, the *F*-statistic testing the null hypothesis of constant intercepts and slopes of the equations measuring the contribution of genetics is 0.39 with 6 and 75 degrees of freedom. Thus, there is no evidence that the change in the tobacco program altered re-

¹¹ Although it typically takes six to seven years to produce genetically stable hybrids, a plant breeder usually has several plant varieties on hand that might serve as candidates for release, so it is not clear how quickly a response by breeders to changed incentives might be observed.

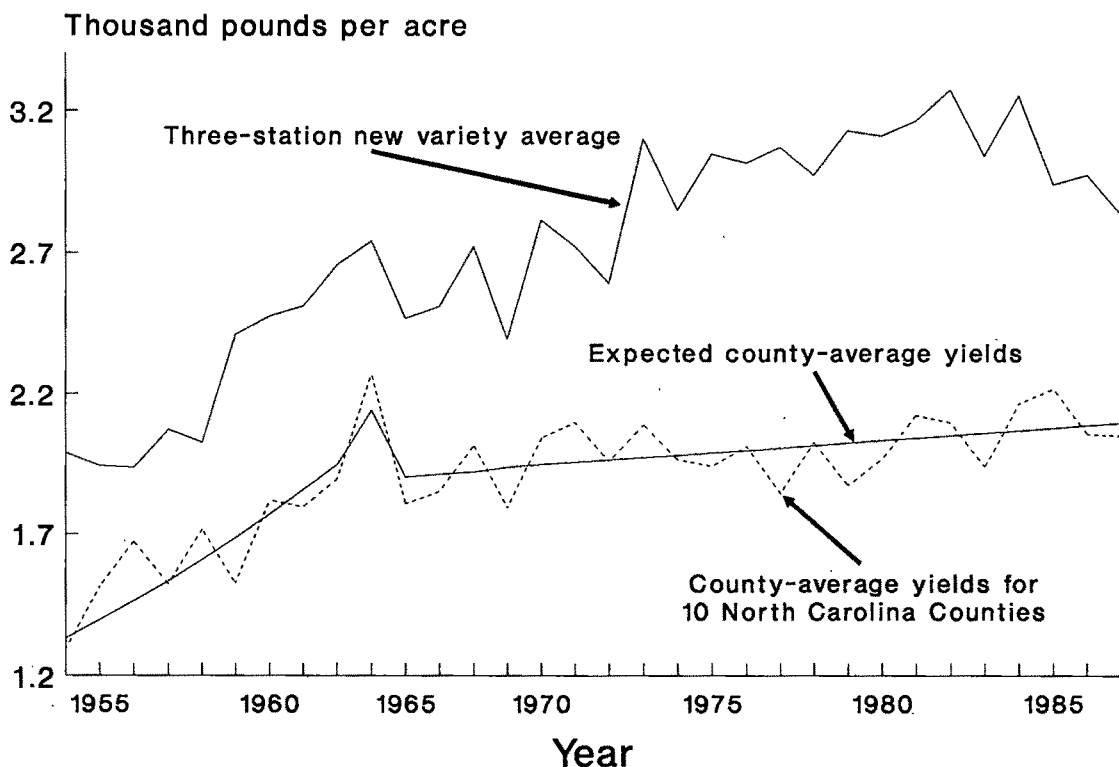

Figure 2. A comparison of county-average yields with research station average yields of new varieties

searchers' delivery of high-yielding varieties beginning in 1965. Indeed, for no year between 1965 and 1978 was the F -statistic testing the null hypothesis of constant intercepts and slopes greater than 1.13.

This negative finding should be interpreted with care. Even though no slowdown in the contribution of genetics could be attributed to the change in the tobacco program, a slowdown in the contribution of yield gains relative to quality gains could occur. The change from acreage allotments to poundage quotas increased the incentives for growers to increase the per pound value of tobacco. Evidence that researchers shifted the mix of yield and quality after the policy change would support the hypothesis that plant breeders do respond to economic incentives felt by their clientele. Such a test is beyond the scope of this study.

The data also allow a test whether the Plant Variety Protection Act (PVPA) of 1970 altered the incentives of tobacco plant breeders similar to the effect on soybean breeders beginning in 1971. No evidence was found that the number of new varieties increased as a result of the PVPA (see table 1). As shown in figure 2, however, the rate of increase of new variety yields in the early 1970s appears to have increased. The basic model presented in table 2 was reestimated eight times allowing for both a shift in the intercepts and a shift in the coefficients on time for eight years after PVPA for the three new variety equations (Perrin, Hunnings, and Ihnen). One year out of eight, 1973, resulted in an F -statistic greater than the 5% critical value of 2.16 with six and 156 degrees of freedom. This evidence is suggestive, but inconclusive, that a response from plant breeders to the adoption of the PVPA may have occurred.

Higher success rates of plant breeding activities after passage of the PVPA would also appear as increases in the genetic contribution to yield increases. As indicated above, however, there is no evidence for a regime change from 1971 to 1978. This finding illustrates the importance of accounting for nongenetic sources of yield variation when testing for changes in the generation of new plant materials. The effect of new cultivars should be estimated as a net effect, not a gross effect.

Conclusion

This paper measures the effect of plant breeding and the development of new varieties on yields

of North Carolina flue-cured tobacco. The main conclusions are as follows: First, genetic innovations have contributed between 20% and 35% of the yield increases on research station plots over the 1954 to 1987 period. Second, recent genetic contributions are small, and the slowdown is not attributable to changes in grower incentives caused by the federal policy shift from land restrictions to marketing restrictions. No evidence suggested that the policy shift, which did have a major effect on grower yields, induced any effective change in new variety research. Third, nongenetic technical change has had differential regional effects, but no regional differences in genetic contribution were found. And last, the establishment of property rights in plant breeding research by the Plant Varieties Protection Act has had no discernable effect on the development of higher yielding flue-cured tobacco varieties.

Using Count Data Models in Travel Cost Analysis with Aggregate Data

Daniel M. Hellerstein

In order to control for censoring and the integer nature of trip demand, the use of count data models in travel cost analysis is attractive. Two such models, the Poisson and negative binomial, are discussed. Robust estimation techniques that loosen potentially stringent distributional assumptions are also reviewed. For illustrative purposes, several count data models are used to estimate a county-level travel cost model using permit data from the Boundary Waters Canoe Area.

Key words: Boundary Waters Canoe Area, count data, negative binomial, Poisson, travel cost.

Estimators of recreational demand models frequently use continuous functional forms, such as ordinary least squares (OLS) on log transformed variables (e.g., Ziemer, Musser, and Hill). However, the nature of trip demand introduces complicating factors. First, trips occur in nonnegative quantities. Failure to control for this censoring will lead to biased estimation. Second, because trips are available only in integer quantities, the usual demand models, which correlate marginal quantity with marginal price, may be inapplicable.

In light of these factors, a natural alternative is to use statistical models that explicitly recognize the "count" nature of trip demand. Several recent papers (e.g., Shaw, Smith, Grogger and Carson, Creel and Loomis) have applied count models to the travel cost model. These works largely have focused on truncated data sets based on choice-based samples. In this study the focus is on the older problem where zero-demanders are included. In particular, the application of several robust estimators of count models to aggregated data will be considered.

The Poisson distribution forms the foundation for the count models examined in this study. Although the Poisson is a convenient distribution

to work with, it imposes some stringent constraints on the demand distribution. In particular, the Poisson distribution assumes the variance of trip demand is equal to the expected value of trip demand. To loosen these constraints, a generalization of the Poisson, the negative binomial, is discussed. Robust estimation procedures, that permit further loosening of a priori assumptions are then reviewed. Permit data from the Boundary Waters Canoe Area are used to examine the effects of these count models on consumer surplus estimates and on coefficient variability.

Theory

In formulating a demand process that yields count data, one must consider that trips are not available in continuous quantities. The integer nature of the data can be explicitly accounted for by modeling the observed number of trips taken (over a season) as the result of many discrete choices (say, one for each day of the season). Under this scenario, count data distributions, such as the Poisson, are an asymptotic outcome.¹

Therefore, in estimating a count model, the analyst is implicitly estimating the "daily" probability of the recreator choosing to visit. Increasing the travel cost will reduce the probability of a visit on any given day. Following Small

Daniel M. Hellerstein is a natural resource economist with the Resources and Technology Division, Economic Research Service, U.S. Department of Agriculture.

Portions of this research were supported by the U.S. Forest Service Rocky Mountain Forest and Range Experiment Station.

The views expressed here are not necessarily those of either the Forest Service or the Economic Research Service.

The author acknowledges Robert Meldelsohn, Michael Moore, George Peterson, and A. Colin Cameron for their advice and assistance.

¹ If the probability of taking a trip on any given day is small, constant and independent of earlier decisions, and if the number of days in a season is large, then the distribution of trips will approach a Poisson process.

and Rosen, integrating over these price changes yields a measure of the compensating variation. Extending these results to the repeated discrete choice context yields a consumer surplus measure over an entire season (Hellerstein and Mendelsohn). The key result is that count data models, as the limit of a repeated discrete choice process, can be used much like continuous models. In particular, integrating under a continuous estimator of predicted demand will yield a measure of consumer surplus.

Given this background, we concentrate on estimating the expected value of trip demand. Furthermore, as a result of repeated discrete choice, the number of observed trips will follow a Poisson distribution. Formally, the expected value of demand is

$$E(Y) = f(P, Z; \beta),$$

where $E(Y)$ is the expected number of trips taken per season, P , Z are explanatory variables including travel cost to site (P) and demand shift variables (Z), such as income and travel costs to substitute sites, and β is a vector of coefficients.

The Poisson probability distribution of demand is

$$(1) \quad \text{Prob}(Y = n; n = 0, 1, 2, \dots) = \exp(-\lambda)\lambda^n/n!$$

with $\lambda = f(P, Z; \beta)$.

The Poisson is a single parameter distribution with expectation and variance both equal to λ (Mood, Graybill, and Boes). Although n is a nonnegative integer, λ must be a strictly positive real number.

The Poisson model is solved by estimating β , say β^* , in $\lambda^* = \lambda(P, Z; \beta^*)$. The estimated value of λ , λ^* , is interpreted as the predicted expected value (and variance) of demand. The predicted expected value of consumer surplus, $E(CS)$, is then computed via the usual integration:

$$(2) \quad E(CS) = \int_{P_{obs}}^{P_{max}} \lambda(P, Z; \beta^*) dP,$$

where P_{obs} is observed price, and P_{max} is a choke price, possibly ∞ .

This paper will focus on this measure of consumer surplus estimated using the predicted mean of demand. Criticisms of this approach in the continuous context (see Bockstael and Strand; or Adamowicz, Fletcher, Graham-Tomasi) stress the importance of considering the source of error. However, if measurement error is small, and

if the measure of expected demand is unbiased, then this measure of consumer surplus will be a good approximation to the expected value of consumer surplus.²

Extending the Poisson: The Negative Binomial

A drawback to the Poisson model is the implied assumption that $E(Y)$ and $\sigma^2(Y)$ are equal. Furthermore, Poisson "regressions" allow no random component in the λ estimator; the $\lambda = \lambda(P, Z; \beta^*)$ relationship does not contain an error component.

The negative binomial count model is often used to relax this unlikely condition of perfect knowledge of the λ estimator and to permit more flexible variance/mean relationships. Following Cameron and Trivedi, the negative binomial is derived as a compound Poisson distribution, where λ is assumed to be distributed as a gamma random variable.³ Integrating over this distribution of λ yields the two parameter negative binomial. Formally,

$$\text{Prob}(Y = n, n = 0, 1, \dots) = \frac{\Gamma(n + \nu)}{\Gamma(n + 1)\Gamma(\nu)} \left(\frac{\nu}{\nu + \mu} \right)^\nu \left(\frac{\mu}{\nu + \mu} \right)^n,$$

with

$$E(Y) = \mu \text{ and } \sigma^2(Y) = \mu + \frac{\mu^2}{\nu}.$$

The variance to mean ratio of the negative binomial is a decreasing function of ν . As ν approaches infinity, the negative binomial collapses to the Poisson; hence the Poisson is nested within the negative binomial.

In terms of the repeated discrete choice framework, the negative binomial admits that

² The concern is that $E(CS(Y))$ may not equal the $CS(E(Y))$, where the latter is what the analyst computes. However,

$$\int_{-\infty}^{\infty} \int_{P_0}^{P_1} d(x; \beta, \epsilon) dP dF(\epsilon) = \int_{P_0}^{P_1} d^*(x; \beta) dP$$

with $d^* = E(Y)$. Therefore, as long as $E(Y)$ is unbiased, then $E(CS(Y))$, the left-hand side of the above equation, will approach $CS(E(Y))$, the right-hand side. It must be stressed that d^* is an unbiased estimate of the expected value of demand. In particular, d^* is assumed to explicitly account for censoring. When this constraint cannot be guaranteed, an alternative form for $d^* = E(Y)$ (such as suggested by Maddala, p. 158) should be used.

³ An alternative derivation can also be found in Hausman, Hall, and Griliches. The Cameron and Trivedi formulation is more flexible, including the Hausman, Hall, and Griliches specification as a special case.

the underlying daily probability of visiting may be randomly distributed. More concisely, each individual is assumed to draw a value for her daily probability at the beginning of the season. Knowledge of the random process generating these daily probabilities is not required, so long as the net result is a gamma distribution of λ , conditional on the exogenous variables.

Estimation

In addition to their appealing statistical properties, the Poisson and negative binomial have several useful empirical properties:

(a) The sum of W independent Poisson variates is also Poisson distributed, with parameter $\lambda_w = \sum_i^W \lambda_i$. Thus, the distribution of visits from the aggregate of W individuals is $\text{prob}(Y = n) = (e^{-\lambda_w})(\lambda_w)^n/n!$. This adding-up property facilitates the use of aggregate data, given knowledge of population size.

(b) If a constant term is included in the function describing λ , the sum (over all observations) of observed demand will equal the sum of predicted demand.

(c) Zero values are admissible. These properties also hold for the negative binomial, with λ replaced by μ .

To insure that λ (or μ in the negative binomial) is strictly positive, it is postulated that

$$(3) \quad \lambda(P, Z; \beta) = \exp(\beta_0 + \beta_P P + \beta_Z Z).$$

These count data models are estimated via maximum likelihood (ML) techniques. The Poisson is readily estimated using the Newton-Raphson technique. The negative binomial, especially its Hessian matrix, is more complicated and is usually solved with a quasi-Newton method, such as the BHHH or the DFP algorithms (Judge et al.).

Maximum likelihood estimation assumes that the postulated distribution is indeed correct. This assumption may impose some stringent requirements, such as the $E(Y) = \sigma^2(Y)$ criteria of the Poisson. The distributional sensitivity of these models raises concerns about robustness. How badly will these models fail if the true probability distribution deviates from the assumed distribution?

The consequences of these assumptions, and possible means of relaxing them, have been studied by a number of authors. For count data models, the work of Gourieroux, Montfort, and

Trognon is especially useful.⁴ They introduce the concept of pseudo- (PML) and quasi-generalized pseudo (QGPML) maximum likelihood estimation. Basically, they show that if functions describing the true mean and true variance of the dependent variable (say, the number of trips) are known [say, equal to $f(p, z; \beta)$ and $g(p, z; \beta, \alpha)$, respectively]; then the Poisson and negative binomial will be consistent, regardless of the underlying distribution. Several interesting results are obtained at the empirical level:

(a) For the Poisson, the estimates of β from ML are consistent, and analytically equivalent to the PML estimates. However, the ML estimate of the covariance matrix of β is too small. The PML estimator can be used to compute a consistent estimate of the covariance (CV) matrix, which turns out to be a function of the "true variance" [the function $g(P, Z; \beta, \alpha)$ introduced above].

(b) For the negative binomial, the ML estimate of β is not consistent if the distributional assumptions do not hold. A two-step QGPML estimator can be used to consistently estimate both α and β . In this case, both β and the CV matrix are functions of the true variance.

An Application to the Boundary Waters Canoe Area

1980 permit data from the Boundary Waters Canoe Area (BWCA) in northern Minnesota will be used to compare the various count models. Each permit contains the ZIP code of the group leader, which can be used to obtain distance-to-site information as well as socioeconomic variables either at the zip code level or at the county level. Because no other information is available, especially information on number of prior trips, the permits must be aggregated. County-level aggregates are used for this analysis. Therefore, the dependent variable is number of trips per county.

A total of 27,433 overnight permits were aggregated into the 1,396 counties within 1,000 road miles of the BWCA.⁵ About half of these

⁴ Other works in this field include White, who offers a general discussion of the consequences of using an incorrect distribution function, and McCullagh and Nelder, who embed count models in the framework of generalized linear models. An interesting summary of count models as weighted, iterative linear estimators is presented by Hall, Hausman, and Griliches.

⁵ All overnight visitors are required to obtain a permit. The entire data base of permits comprises a full census of overnight visitors, who account for about 50% of BWCA use (in RVD terms).

counties have zero visits. Travel cost was based on \$0.076/mile (1980\$) plus a time cost computed using one-third of the per capita wage rate multiplied by average group size (4.0); the result was an average cost per mile of approximately \$0.20.

Table 1 contains the results from several models. An exponential form is used, with an individual's expected demand equal to $\exp(X\beta)$, where X is a vector of exogenous variables. Because aggregate data are used, the population of each county must also be considered. For the count models, the adding-up property suggests use of population as a multiplicative weight. Thus, $E(Y_{\text{county}}) = POP * \exp(X_{\text{county}}\beta)$; Y_{county} is the aggregate number of visits from the county, POP is the population of the county, and X_{county} is a set of county-level exogenous variables (see table 1 for a description of the exogenous variables). For comparative purposes, a simple per capita semilog model is also estimated. Consumer surplus (CS) estimates (in 1980\$) are computed using equation (2), with equation (3) used for λ^* .⁶ In all models, the reported CS estimates use all 1,396 counties.

The most noticeable results are that the own-price coefficient ($BWTC$) is negative and significant for all models. This is especially true for the Poisson model. However, if the Poisson assumption of $E(Y) = \sigma^2(Y)$ is incorrect, then the standard errors generated by the ML estimator of the Poisson will also be incorrect. To test this assumption, a score test devised by Lee is computed. This test is normally distributed under the null hypothesis that the Poisson model is correct. The results of this test, and the large value of the t -statistic for α in the negative binomial model, indicate that the Poisson is inappropriate [that $E(Y)$ does not equal $\sigma^2(Y)$]. Thus, the CV matrix computed by the ML estimator is incorrect, suggesting use of the PML estimator for the Poisson model. In the PML estimator, $BWTC$ is still significantly negative, but several of the demand shifters (the age variables, percent unemployment, and percent poverty) are insignificant at the 95% level.

The negative binomial model returns qualitatively similar coefficients for $BWTC$, % COL -

$LEGE$, and $INCOME$. The sign on the substitute price ($APTC$) is now positive, the theoretically anticipated sign. Also, the age variables are significant.

Within count models, the effect on consumer surplus is on the order of 25%. A much greater change (50%–100%) occurs between count and semilog OLS models. In RVD terms, given an average CS of \$1.5 million, and a total of 25,000 groups of four individuals spending four days in the wilderness, the average RVD value will be about \$4.00 (a fairly small value).

The semilog OLS model uses two heuristics: zero observations are dropped when coefficients are computed, and a bias correction factor is computed. The drop zeros rule ensures computability of the model. Since it discards information about nonvisitors, a potential for bias exists. Alternatively, the semilog model could be estimated using a nonlinear maximum likelihood technique (Creel and Loomis). While such an approach permits zero visits, the treatment of demand shocks resulting from fluctuations in the error term (presumably caused by changes in unobservable factors) is not consistent with demand shocks caused by fluctuations in observed exogenous variables; with changes in unobservable factors having an additive impact, changes in observable variables have a proportional impact. Although this feature may or may not be appealing, for purposes of comparison the simpler drop zeros method is adopted.

The bias correction factor (Stynes, Peterson, and Rosenthal) is a simple multiplier guaranteeing that the sum of observed demand equals the sum of predicted demand. It has substantial impact, leading to a doubling of CS . Alternatively, Bockstael and Strand argue against inclusion of such a bias correction factor. However, the bias correction factor is used since unbiased estimation of $E(CS)$ requires an unbiased estimate of $E(Y)$.

Formal qualitative comparisons between models are presented in table 2 and by examining the η^2 goodness-of-fit statistic in table 1.⁷ Table 2 displays the results of an out-of-sample test created by Ashley and popularized by Shaw.

⁶ To maintain consistency with the definition of the market area (all counties within 1,000 miles), a choke price equal to the maximum price in the sample is used. Alternatively, a choke price of infinity could be used. However, when CS is computed using a choke price of infinity, the results differ by less than 1%. Note that the market area is limited in order to limit the bias resulting from visitors who partake in multiple-destination trips.

⁷ The η^2 statistic can be described as a measure of the correspondence between observed and predicted values. It is related to the familiar R^2 statistic. Specifically, $R^2 = ESS/TSS$ and $\eta^2 = 1 - RSS/TSS$, with ESS the explained sum of squares, TSS the observed (total) sum of squares, and RSS the residual sum of squares. In linear models, these two statistics are analytically equivalent, but they may diverge in nonlinear models. For further discussion of goodness of fit statistics in nonlinear models, see Peterson and Stynes.

Notes: Dependent variable: count models, number of visits per county; semilog OLS model, per capita visitation. Functional form (W = population): for count models, $E(Y) = W \cdot \exp(X\beta)$; for semilog OLS, $E(\ln(Y/W)) = X\beta$. Here, 27,433 permits are aggregated by county into 1,396 observations. Of these 1,396 observations, 647 observations contain zero visits (zero permits). T -statistics are displayed in parenthesis. For Poisson and QGPMML count models, the standard errors are computed using the inverse Hessian. The negative binomial ML uses $\ln(Z'/Z)$, with $Z = \partial L / \partial \beta$. Independent variables: BWTC is travel cost to BWCA; APTC, travel cost to Algonquin Provincial Park, a substitute site in southern Ontario; INCOME, per capita income; %UNEMPLOY, % of labor force currently unemployed; %COLLEGE, % of population older than 16 with college degree; %POVERTY, % of households with income below poverty level; % < 17, % of population less than 17 years old; and % > 65, % of population greater than 65 years old. The GAUSS programs used to estimate these models are available from the author.

^a The Poisson ML and the Poisson PML models yield analytically equivalent estimates of β .

^b The NEGBIN II model is used, with the variance to mean ratio linear-in-the-mean: $\sigma^2(y) = E(y)[1 + \alpha E(y)]$.

^c A bias correction factor of 0.74, computed to force the sum of predicted visits to equal the sum of observed visits is incorporated into the constant.

^d For the PML Poisson and the QGPMML Negative Binomial, α is computed in separate regression; it is not estimated using the likelihood function, hence standard errors are not available. Note that in the MLE negative binomial, α insignificantly different from 0 implies that the variance equals the mean.

^e Under the null hypothesis the Poisson is the correct distribution, implying that the mean equals the variance, the Lee test (Lee) is distributed as a standard normal. A one-tailed test is appropriate, with critical value at 1.64.

Table 2. Ashley Test of Model Quality

Model 1 ^a	Model 2	The superior model is . . .
Poisson	NegBin	inconclusive
Poisson	QGPML	inconclusive
Poisson	Semilog+	Poisson
NegBin	QGPML	NegBin
NegBin	Semilog+	NegBin
QGPML	Semilog+	QGPML

Note: The Ashley test (Ashley, or Shaw) uses out-of-sample data (1981 data) to directly compare the predictive power of two different models.

^a Models: Poisson, Poisson model; NegBin, negative binomial estimated using ML; QGPML, negative binomial estimated using QGPML; Semilog+, OLS on semilog model with a "bias correction" factor.

This test is essentially a nonparametric comparison of the goodness of fit of two different models, using out of sample data. In this case, 1981 data are used as the out-of-sample data, and 1980 data are used to estimate the coefficients.⁸

The η^2 goodness-of-fit statistics suggest that fit is fairly good, especially for the Poisson model. The negative binomial have predictive accuracy similar to the bias-corrected semilog. The results of the Ashley test, although not conclusive, suggest that count models are superior to the bias-corrected semilog model. Within count models, the evidence is weaker. For example, the ML negative binomial is considered superior to the QGPML negative binomial. It is interesting that a Hausman specification test (Hausman) comparing the QGPML and the ML estimators fails to reject the consistency of the ML estimator; the result indicates that the negative binomial distribution is correct.

These results indicate that count models outperform the drop-zeros semilog model. Within count models, the Poisson outperforms the negative binomial in predictive accuracy but produces incorrect measures of variability, throwing the Poisson t -statistics into doubt. The PML estimator of the Poisson can be used to address this failure while maintaining the predictive power of the Poisson. The QGPML negative binomial is similar to the ML negative binomial, suggesting either that the ML estimator be used (on

efficiency grounds) or that the QGPML estimator be used (on ease of computation grounds).

Concluding Comments

The intrinsic nature of site visitation suggests that demand models based on continuous functional forms are inappropriate because they fail to recognize the count nature of trip making. To account for this feature, two count models, the Poisson and negative binomial, are reviewed. At an empirical level, besides matching the integer quality of trip demand, these count distributions explicitly account for censoring at zero. Furthermore, a behavioral justification for their use, based on a repeated discrete choice process generating trip demand, can be derived.

An application to permit data from the Boundary Waters Canoe Area reveals that the choice of estimator can have substantial impact, especially on consumer surplus estimates. In particular, the drop-zero semilog OLS yielded estimates approximately 50% larger than the Poisson. The consumer surplus differences among the several count models were smaller. This suggests that for welfare purposes, the ML Poisson may be adequate. However, coefficient values did vary, especially for demand shift variables. More important, t -statistics for all variables were quite different across count models, with the robust estimators (such as the PML Poisson) generally returning much smaller t -statistics. These results suggest caution when interpreting coefficient values from maximum likelihood estimators.⁹

Although the application of count models to travel cost analysis is becoming increasingly popular, the existence of robust estimators for both the Poisson and negative binomial has not been exploited. These robust estimators reduce the extent of a priori knowledge required for consistent estimation of the coefficient vector and its covariance matrix.

A discussion of the aggregation issue also is in order. First, consider the robust estimators used here. They all require that the functional form describing expected demand is correct. In the context of aggregate data, this requires that the

⁸ The Ashley test uses out-of-sample data. To test that 1981 data is out of sample but not generated by a different model, parameter stability is tested. Specifically, a Chow test of parameter equality, using 1980 and 1981 data with a Poisson PML model, failed to reject the null of parameter stability; with an $F(9, 2774)$ -statistic of 0.92, well below the 95% cutoff level at 1.88. However, the MLE model did reject the null, with an F -statistic of 42.0.

⁹ To the extent that variance of consumer surplus is a function of the covariance of the coefficient vector, this result also suggests caution when qualitative comparisons are formed. See Bockstael and Strand or Adamowicz, Fletcher, and Graham-Tomasi for further discussion of the effects of uncertainty on the variance of consumer surplus estimates.

X_{county} measures be representative, in the sense of Deaton and Muelbauer (p. 149), of the county. If they are not, then $W^* \exp(X_{\text{county}}\beta^*)$ will not equal $\sum_{i=1}^W \exp(x_i\beta^*)$, and the requirements for robust estimation will be violated.

This weakness of aggregate data sets must be measured against the weaknesses of alternative methods, such as the sample selection models of Shaw or the truncated count models of Creel and Loomis. These models admit the influence of nonvisitors in a limited fashion. First, for tobit-like estimators and for Poisson-based models, incorrect specification of higher moments will bias estimates of demand parameters. Although the negative binomial is robust to misspecification of higher moments (Grogger and Carson), all these models are sensitive to the presumption that nonvisitors possess the same demand parameters as visitors. To the extent that this is not true, truncated models may be more biased than aggregated models. In other words, aggregate models permit nonvisitors to influence estimation, so that the resulting parameters are a reduced form incorporating information on both visitors and nonvisitors. For many purposes, such as calculating the CS for a new population, such parameters may be superior to those produced by truncated models.¹⁰ In short, aggregate analysis is not necessarily dominated by site-based samples estimated with econometric techniques that recognize truncation.

A Model of Production with Supply Management for the Canadian Agricultural Sector: Comment

Carl H. Nelson

In a recent paper Moschini (1988) claims to prove that cost complementarities between outputs do not exist when outputs are joint because of fixed allocatable factors which are normal inputs. This comment demonstrates that Moschini's proposition is incorrect, shows where the proof of the proposition is faulty, and identifies the additional condition that must hold in order for Moschini's proposition to be true. Correct derivation of this proposition is important because technology with fixed allocatable factors and multiple outputs is common in agriculture and standard analyses of multiple output cost functions, such as Sakai's or Lau's, do not apply directly to this technology.

Consider the multiple output cost function used in Moschini (1988) to characterize production which is joint in outputs because of constraints on allocatable fixed factors. Jointness is not present in the primal representation of this technology. The production possibility set can be represented with individual production functions for each output. But outputs are joint in the dual cost and profit functions because they must compete for a constrained quantity of some allocatable input. The joint cost function is defined by Moschini's equation (15), which is reproduced here as equation (1):

$$(1) \quad C(y, w, z) = \min_{(z^i)} \left\{ \sum_i C^i(y_i, w, z^i) \mid \sum_i z^i \leq z \right\},$$

where $y = (y_1, y_2, \dots, y_n)$ is the vector of outputs, w is the vector of prices for variable inputs, z is a scalar representing the total amount of the fixed input that can be allocated to production of the various outputs, and z^i , $i = 1, 2, \dots, n$ is the amount of the fixed input allocated to output i . The joint cost function $C(y, w, z)$ is assumed to be twice continuously differentiable in its arguments. This implies that each of the individual cost functions is twice continuously differentiable in its arguments. And it is assumed that the solution to (1) occurs in the interior of the feasible region.

Carl H. Nelson is an assistant professor, Department of Agricultural Economics, University of Illinois.

This research is part of Project No. 05-334 of the Illinois Agricultural Experiment Station.

The helpful comments of David S. Bullock and three anonymous referees are gratefully acknowledged.

Moschini claims to prove that, given these assumptions and the additional assumption of normal fixed inputs (i.e., $\partial^2 C^i / \partial y_i \partial z^i \leq 0$), cost complementarities between outputs do not exist (i.e., $\partial^2 C / \partial y_i \partial y_j \geq 0$). The proof of this claim appears in Moschini's equations (17) through (19). The error in the proof occurs in equation (18). Moschini's equation (18) is a standard primal comparative static result obtained by totally differentiating the first-order conditions from the cost minimization problem defined in equation (1). A correct derivation of this comparative static result follows.

The first-order conditions for the problem in equation (1) are $\partial C^i / \partial z^i = \theta$ $i = 1, 2, \dots, n$ and $\sum_i z^i = z$, where $\theta = \partial C / \partial z$ is the negative of the quasi-rent of the fixed input z . Total differentiation of these equations with respect to the choice variables, θ , z^1 , z^2 , \dots , z^n , and the exogenous variables z , y_1 , y_2 , \dots , y_n yields

$$(2) \quad \begin{bmatrix} 0 & -1 & -1 & \cdot & \cdot & \cdot & -1 \\ -1 & C_{zz}^1 & 0 & 0 & \cdot & \cdot & 0 \\ \cdot & 0 & C_{zz}^2 & 0 & \cdot & \cdot & 0 \\ \cdot & \cdot & 0 & \cdot & 0 & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ -1 & 0 & \cdot & \cdot & \cdot & \cdot & C_{zz}^n \end{bmatrix} \begin{bmatrix} d\theta \\ dz^1 \\ dz^2 \\ \cdot \\ \cdot \\ dz^n \end{bmatrix} = \begin{bmatrix} -1 & 0 & 0 & \cdot & \cdot & \cdot & 0 \\ 0 & -C_{zy}^1 & 0 & \cdot & \cdot & \cdot & 0 \\ \cdot & 0 & -C_{zy}^2 & 0 & \cdot & \cdot & 0 \\ \cdot & \cdot & 0 & \cdot & 0 & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ 0 & \cdot & \cdot & \cdot & \cdot & 0 & -C_{zy}^n \end{bmatrix} \begin{bmatrix} dz \\ dy_1 \\ dy_2 \\ \cdot \\ \cdot \\ dy_n \end{bmatrix},$$

where $C_{zz}^i = \partial^2 C^i / \partial z^i \partial z^i$, and $C_{zy}^i = \partial^2 C^i / \partial y_i \partial z^i$. The derivative defined in Moschini's equation (18), $\partial z^i / \partial y_m$, can be obtained by premultiplying both sides of equation (2) by the inverse of the matrix on the left-half side of the equation. As is standard in such comparative static derivations the matrix on the left-hand side of the equation is the bordered Hessian of the objective function. The second-order condition of the optimization problem in (1) requires that this matrix be positive definite subject to one constraint, which implies that all border-preserving principal minors of the bordered Hessian must be negative.

Because the matrix on the right-hand side of equation (2) is diagonal the solution for $\partial z^i/\partial y_m$ will only involve the term in the i th row and m th column of the inverse of the bordered Hessian. Letting A represent the diagonal matrix in the lower right-hand corner of the bordered Hessian and ι a column vector of 1's, partitioned inversion allows the inverse of the bordered Hessian to be written as: $[A^{-1} - A^{-1}\iota\iota'A^{-1}/(\iota'A^{-1}\iota)]$, yielding the result that the (i, m) th element of the inverse of the bordered Hessian is

$$(3) \quad \frac{1}{C_{zz}^i C_{zz}^m \left(\sum_{k=1}^n \frac{1}{C_{zz}^k} \right)}$$

for i and m between 2 and n . This means that the correct expression for $\partial z^i/\partial y_m$, instead of Moschini's equation (18), is

$$(4) \quad \partial z^i/\partial y_m = \frac{(\partial^2 C^m/\partial z^{m*}\partial y_m)}{\partial^2 C^i/\partial z^i\partial z^i\partial^2 C^m/\partial z^{m*}\partial z^{m*} \left(\sum_{k=1}^n \frac{1}{\partial^2 C^k/\partial z^{k*}\partial z^{k*}} \right)}.$$

The error in Moschini's argument is the claim that second-order conditions and input normality require the expression in (4) to be negative. While it is true that the assumption of input normality requires the numerator of (4) to be negative, it is not true that second-order conditions require the denominator of (4) to be positive. The second-order conditions allow one of the second derivatives, $\partial^2 C^j/\partial z^j\partial z^j$, to be negative as long as it is smaller in absolute value than all other such second derivatives. This means there are three conditions under which the denominator of (4) can be negative. First, $\sum_{k=1}^n 1/(\partial^2 C^k/\partial z^{k*}\partial z^{k*})$ can be negative if $1/(\partial^2 C^j/\partial z^j\partial z^j)$ for some j not equal to i or m is negative and larger in absolute value than $\sum_{k \neq j}^n 1/(\partial^2 C^k/\partial z^{k*}\partial z^{k*})$. Second, $\sum_{k=1}^n 1/(\partial^2 C^k/\partial z^{k*}\partial z^{k*})$ can be negative if $1/(\partial^2 C^i/\partial z^i\partial z^i)$ is negative and smaller in absolute value than $\sum_{k \neq i}^n 1/(\partial^2 C^k/\partial z^{k*}\partial z^{k*})$. Or third, $\sum_{k=1}^n 1/(\partial^2 C^k/\partial z^{k*}\partial z^{k*})$ can be negative if $1/(\partial^2 C^m/\partial z^{m*}\partial z^{m*})$ is negative and smaller in absolute value than $\sum_{k \neq m}^n 1/(\partial^2 C^k/\partial z^{k*}\partial z^{k*})$. Contrary to Moschini's claim, each of these conditions is allowed by the second-order conditions for the problem defined in equation (1).

The expression in equation (4) is negative, and Moschini's proposition about cost complementarity is true if an additional restriction is imposed upon Moschini's model. The additional restriction is that each of the single output cost functions be convex in z . This assumption requires all of the second derivatives, $\partial^2 C^j/\partial z^j\partial z^j$, to be positive. Assuming convexity of all the single-output cost functions is the same as assuming that all the single-output production functions are concave in z . This assumption implies that the production possibility set is a convex set, which is the sufficient condition for a profit-maximizing choice of fixed and variable inputs to be a long-run equilibrium. Thus, Moschini's proposition

holds when the sufficient conditions for long-run equilibrium hold.

But, jointness caused by fixed allocatable factors is likely to be of greatest interest when fixed assets are not in long-run equilibrium. And there is reason to believe that some fixed assets in agriculture are in disequilibrium. Nelson, Braden, and Roh find evidence that aggregate agricultural machinery and tractors are not in long-run equilibrium. When an asset is not in long-run equilibrium, the only theoretical restriction on $\partial^2 C^i/\partial z^i\partial z^j$ comes from the second-order conditions for an interior solution to (1). And these second-order conditions do not require $\partial^2 C^i/\partial z^i\partial z^j \geq 0$ for all i . That is, they do not require that all of the individual cost functions be convex in z^j . Rather, they rule out "too much" concavity in z^j . In other words, if the cost function for one of the outputs decreases

too rapidly in z , or more than one single output cost function is concave in z , then the first-order conditions for an interior solution do not describe a cost-minimizing fixed input allocation. But, as long as none of the individual cost functions decreases too rapidly in z , an interior solution with joint production is consistent with concavity of one of the single output cost functions in z .

Insight into the restrictions on concavity that are imposed by the second-order conditions can be gained from the following simple three-output example. If $\partial^2 C^1/\partial z^1\partial z^1 = 2$, $\partial^2 C^2/\partial z^2\partial z^2 = -4$, and $\partial^2 C^3/\partial z^3\partial z^3 = 6$, the second-order conditions for cost minimization are violated; but if $\partial^2 C^1/\partial z^1\partial z^1 = 2$, $\partial^2 C^2/\partial z^2\partial z^2 = -1$, and $\partial^2 C^3/\partial z^3\partial z^3 = 6$ the second-order conditions are satisfied and $\partial^2 C/\partial y_1\partial y_3 \leq 0$. Intuitively, this derivative is negative because an exogenous increase in y_3 causes an increase in z^3 and a larger-than-offsetting decrease in z^2 , because of the decrease in the quasi-rent, $q(y, w, z)$, of z . An exogenous increase in the amount of y_3 decreases the quasi-rent of z because an increase in y_3 reallocates z to less valuable uses. The additional z freed by the reduction in z^2 is used to increase z^1 , which reduces $\partial C/\partial y_1$.

If z were in long-run equilibrium, the quasi-rent of z would equal the market price of z , r , and $\partial C/\partial z^j$ would equal $-r$ for all i . Further, the second-order condition for cost minimization would require that $\partial^2 C^i/\partial z^i\partial z^j \geq 0 \forall i$. The fact that the cost of producing a given output can be concave in a fixed input, while it must be convex in variable inputs has bearing on the argument in Moschini (1989) claiming to demonstrate that $\partial^2 C(y, w, r)/\partial y_i\partial y_j \geq 0 \forall i \neq j$. The Moschini (1989) argument for the absence of cost complementarities is critically dependent on the assumption that the production possibility set is convex in the fixed inputs, z . As with Moschini (1988), the

Moschini (1989) argument is not valid if the sufficient conditions for long-run equilibrium, a convex production possibility set, are not satisfied.

The dependence of the Moschini (1989) argument on this assumption highlights the fact that Lau's Hessian identity results must be applied with care to agricultural production. Lau's claims about properties of the Hessians, in particular the claim that the restricted profit function is concave in z , depend upon the assumption that the production possibility set is convex in z . When fixed assets are not in long-run equilibrium convexity may be violated, as it is if one of the individual production functions is not concave in z . Under such conditions, neither Sakai's normal case nor Moschini's proposition about cost complementarity correctly describes the cost and profit interactions between multiple outputs. The derivatives, $\partial^2 C^i / \partial z^j \partial z^l$, are important parameters for technologies joint in outputs because of fixed allocatable factors. The signs of these parameters should be determined

empirically in order to understand the nature of technology joint from fixed allocatable factors.

A Model of Production with Supply Management for the Canadian Agricultural Sector: Reply

Giancarlo Moschini

Nelson correctly points out an error in equation (18) of Moschini (1988). The formula that I gave is valid for the two-output case; but, for the general n -output case, the correct expression is given by Nelson's equation (4). I should be thankful for his careful reading of my paper. Regrettably, Nelson goes on to make a number of erroneous inferences which lead to unfounded criticisms of my analysis. I will show that the result he questions is valid without any stronger conditions than those contained in my paper. In particular, Nelson confused two basic properties of production technologies. He claims that my result requires concavity of the production function when, in fact, it is valid as long as the production function is quasi-concave. Below, I will prove that quasi-concavity suffices, and I will show that violation of quasiconcavity leads to inconsistent definitions of input normality. Finally, I will show that Nelson's analysis of the relationship of my results to long-run equilibrium conditions is incorrect.

The context is a multiproduct firm with an allocatable fixed input z , n production lines with individual production functions $y_i = f^i(x^i, z^i)$, where (x^i, z^i) are inputs allocated exclusively to the i th production line, and where one of the inputs must satisfy the constraint $\sum_i z^i \leq z$. In this setting, under weak regularity conditions and given a vector of variable input prices w , one can define individual cost functions $C^i(y_i, w, z^i)$ and a joint cost function $C(y, w, z)$, where y is the vector of n outputs (Moschini 1988). If the regularity conditions of the production process are strengthened by assuming that the input z is normal, I claimed that $\partial^2 C / \partial y_i \partial y_m \geq 0$ for all $i \neq m$. Nelson disputes this result with arguments that revolve around the second-order conditions (SOCs) for problem (15) of Moschini (1988). My own reference to the same SOCs was unnecessary,¹ but the use he makes of them is unacceptable.

Nelson's argument crucially hinges on the claim that the individual cost functions may be concave in

the fixed input, i.e., it is possible to have $\partial^2 C^i / \partial z^i \partial z^i \leq 0$. To understand what this means, it should be clear that $(-\partial C^i / \partial z^i) \equiv r^i(y_i, w, z^i)$ is the shadow price of the fixed input in the i th production line. Hence, Nelson allows this shadow price to be increasing in the quantity of fixed input, i.e., the implicit demand of the fixed input may be upward sloping. One may well wonder under what production conditions this startling feature is admissible. Nelson says that this will happen when the production function is not concave, and he states: "Assuming convexity of all single-output cost functions is the same as assuming that all single-output production functions are concave in z ." Contrary to Nelson's claim, this is not true.

The error in Nelson's argument can be seen by considering the simple counterexample of a Cobb-Douglas production function with only one variable input and one fixed input: $y = xz^2$. This production function is not concave in z , yet the associated cost function is $C = ywz^{-2}$, which is convex in z . In fact, it can be shown that the cost function C^i can be concave in z^i only if the production function violates the property of quasiconcavity. This is seen in the two-input case illustrated in figure 1. If there is only one variable input x and one fixed input z , the shadow price of z can be measured in terms of how much x can be saved as z is varied. In other words, the shadow price of z is the marginal rate of technical substitution multiplied by the variable input price. Hence, for the shadow price to be increasing in z , this marginal rate of technical substitution must be increasing, which means that the technology violates quasiconcavity as is the case for point A in figure 1.

Because this issue is of wider interest, a more rigorous and general proof is warranted. One can prove the following:

PROPOSITION. *If the production function $f^i(x^i, z^i)$ is quasiconcave, the corresponding cost function $C^i(y_i, w, z^i)$ is convex in z^i .*

To prove this, let z_1^i and z_2^i be two distinct levels of the fixed input.² Let x_1^i and x_2^i be the corresponding cost minimizer variable input vector for the output level y_i such that $C^i(y_i, w, z_1^i) \equiv wx_1^i$ and $C^i(y_i, w, z_2^i) \equiv wx_2^i$. Now define $z_0^i \equiv [\lambda z_1^i + (1 - \lambda)z_2^i]$ for $\lambda \in (0, 1)$. Note that, if the production function $f^i(x^i, z^i)$ is quasiconcave, then $[\lambda x_1^i + (1 - \lambda)x_2^i, z_0^i]$ can

Giancarlo Moschini is an associate professor of economics, Iowa State University.

This is Journal Paper No. J-14315 of the Iowa Agriculture and Home Economics Experiment Station, Project No. 2953.

The author thanks Harvey Lapan for his helpful comments.

¹ The SOCs in fact do require the denominator of my equation (18) to be positive. Although justifiable in this sense, reference to the SOCs was unnecessary because, as shown below, standard regularity conditions or a proper definition of input normality are sufficient. In any case, I did not claim, contrary to what is suggested by Nelson, that the SOCs require the denominator of his equation (4) to be positive.

² Note that this proof does not require z^i to be a scalar; hence, the proposition given is valid for the case of many fixed inputs.

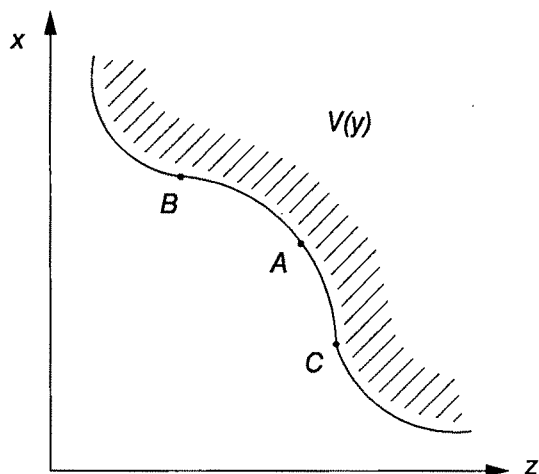

Figure 1. Not quasi-concave technology

feasibly produce y_i (the input requirement set is convex). However, in general this is not the cost minimization solution. Let x_0^i be the cost minimizer when the fixed input is z_0^i . Hence, it must be that $w x_0^i \leq w[\lambda x_1^i + (1 - \lambda)x_2^i]$. By definition $C^i(y_i, w, z_0^i) \equiv w x_0^i$; thus, it follows that:

$$(25) \quad C^i(y_i, w, z_0^i) \leq \lambda C^i(y_i, w, z_1^i) + (1 - \lambda)C^i(y_i, w, z_2^i),$$

which establishes that the cost function is convex in the fixed input. If the production function is strictly quasiconcave, then the cost function $C^i(y_i, w, z^i)$ is strictly convex in z^i . Moreover, if all individual cost functions are convex in z^i , then the joint cost function defined by (15) will be convex in z .³

Nelson's failure to distinguish quasiconcavity from concavity is misleading because quasiconcavity is a much weaker assumption than concavity. Quasiconcavity of the production function implies nonincreasing marginal rates of substitution between inputs and is equivalent to the input requirement set $V(y)$ being convex (the isoquants have the usual convex-to-the-origin shape). It does not imply concavity of the production function, and it does not rule out increasing returns in production (the production possibility set need not be convex). Indeed, the Cobb-Douglas example given above displays increasing returns to scale. When quasiconcavity is violated, some appealing properties of production technologies are ruled out. For example, one may produce a unit of output with the input combinations of either point B or point C in figure 1, but one cannot produce the same unit of output by combining the two production processes

(point on the line segment between B and C are not feasible.)

I have shown that Nelson's argument crucially depends on the violation of the basic regularity condition of quasiconcavity. Because in Moschini (1988) I assumed input normality, I will now argue that for a meaningful definition of a normal input one must be dealing with a quasiconcave technology. The definition of a normal fixed input that Nelson and I use is to require that $\partial^2 C^i / \partial y_i \partial z^i \leq 0$ (for every production line, the shadow price of the fixed input is nondecreasing in output, or, alternatively, the marginal cost is nonincreasing in the fixed input). By itself, however, this is not enough. The standard definition of a normal input requires that the cost-minimizing input demand increases with output (Chambers, p. 69).⁴ Put another way, the output expansion path is not backward bending. When quasiconcavity is violated at the fixed input level z^i , then no expansion path passes through the input allocation point. Thus, the definition of a normal fixed input in terms of $\partial^2 C^i / \partial y_i \partial z^i \leq 0$ is dual to the standard definition only if the technology is quasiconcave. Indeed, the notion of input normality is meant to strengthen the usual regularity conditions, not to weaken them. Hence, I believe that the assumption of quasiconcavity was not only implicit in my analysis but also necessarily implied by my explicit assumption of input normality.

The inconsistency of Nelson's purported assumption of a normal input when quasiconcavity of the production function is violated can be illustrated by a further implication of the case at hand. Recall that input normality in terms of $(-\partial^2 C^i / \partial y_i \partial z^i) = \partial r^i / \partial y_i \geq 0$ implies that the shadow price of the fixed input is nondecreasing in output for all production lines. But what about the shadow price of the same input viewed from the point of view of the whole firm? This shadow price is given by $(-\partial C / \partial z) \equiv r(y, w, z)$, and in equilibrium one must have $r(y, w, z) = r^i(y_i, w, z^{i*})$. This shadow price is simply the negative of the Lagrange multiplier of the problem in my equation (15) [in Nelson's equation (2) this multiplier is θ]. Hence, the question hinges on the sign of $\partial r / \partial y_i = -\partial^2 C / \partial y_i \partial z$. Differentiating the first-order conditions of problem (15) and solving yields

$$(26) \quad \frac{\partial r}{\partial y_i} = - \frac{\frac{\partial^2 C^i}{\partial y_i \partial z^i}}{\frac{\partial^2 C^i}{\partial z^i \partial z^i} \left(\sum_{k=1}^n \frac{1}{\frac{\partial^2 C^k}{\partial z^k \partial z^k}} \right)}.$$

Now, the SOC's for an interior solution of problem (15) allow at most one of the individual cost func-

³ Hence, quasiconcavity of the individual production functions (convexity of the cost functions in the fixed input) means that the curvature conditions for a global minimum for problem (15) are satisfied. One should be careful in using SOC's when the curvature conditions do not necessarily hold because the SOC's only characterize a local optimum. In the present case, if one of the cost functions is allowed to be concave in the fixed input, as Nelson does, there is no guarantee that there exists only one minimum.

⁴ This is the definition given in Moschini (1988). According to another definition, which follows Hicks' discussion of a regressive input, an input is normal if its profit-maximizing demand increases when the output price increases. When the conditions for profit maximization are satisfied, this definition will always imply the previous one.

tions to be concave in the fixed input but require all bordered principal minors of the Hessian to be negative. Note that the n th bordered principal minor in our case is

$$(27) \quad - \left(\prod_{k=1}^n \frac{\partial^2 C^k}{\partial z^k \partial z^k} \right) \left(\sum_{k=1}^n \frac{1}{\frac{\partial^2 C^k}{\partial z^k \partial z^k}} \right).$$

If one of the cost functions is concave in the fixed input, then one must have $[\sum_k (\partial^2 C^k / \partial z^k \partial z^k)^{-1}] < 0$ to satisfy the SOC's. Nelson fails to realize this and gives an incorrect characterization of his own equation (4).⁵ This also means that violation of quasiconcavity for one of the production functions, say the j th, while requiring normality in the sense of $\partial r^j / \partial y_i > 0$ ($\forall i$), implies that $\partial r / \partial y_i < 0$ for all $i \neq j$. Thus, in Nelson's setting one has the paradox of a fixed input that is meant to be normal in all production lines but that is globally inferior in $(n - 1)$ outputs!⁶

Nelson's discussion concerning the relationship of my result to long-run equilibrium conditions is not sound. First of all, because the necessary technological assumption is quasiconcavity, this can relate only to the conditions of long-run cost minimization and not to the conditions of long-run profit maximization discussed by Nelson. More important, it must be recognized that equilibrium is not simply a technological concept and that the properties of the technology provide necessary but not sufficient conditions for long-run equilibrium to hold. For example, if the allocatable fixed input in question is land, a farm may not be at its long-run equilibrium size because of credit constraints, notwithstanding the properties of its production functions (which may, in fact, be quasiconcave). In other words, one cannot infer from observation of disequilibrium that the technological conditions necessary for equilibrium have been violated. In particular, whether or not a fixed input is in equilibrium in the sense of earning the market rate of return is irrelevant for the purpose of understanding the properties of the technology. In the present case, what matters is not whether a fixed input level would be chosen as optimal at the current market rate of return; rather, what matters is whether the level of fixed input could have been chosen as optimal at some appropriate rate of return (i.e., its shadow price).

Nelson's passing comments on Moschini (1989) are similarly without ground. For the sake of clarity, I

will note that in Moschini (1989) I did make the explicit assumption that the individual production functions are concave. This assumption allowed me to generalize the results to profit-maximization conditions and to prove that with allocatable fixed inputs and input normality the supply of any one output is inversely related to the price of any other output.

In conclusion, I have reaffirmed the validity of a result presented in Moschini (1988). Related results were presented in Moschini (1989), and some final thoughts on their relevance are in order. In my analysis I developed the normal case of multioutput production with allocatable fixed factors. An alternative normal case of joint production characterized by Sakai has received considerable attention in the applied agricultural production literature (see, e.g., Hertel, Ball). However, as shown in my work, the case of allocatable fixed factors produces very different conclusions. My results should be of interest for two main reasons. First, my analysis is consistent with the distinctive land allocation problem typical of agricultural production both at the farm and aggregate levels. Second, the assumption that inputs are normal is eminently reasonable for many empirical applications.⁷ Hence, I believe that my results provide a benchmark that is interesting in its own right and that should prove useful in assessing empirical findings and in discriminating among multioutput production structures.

⁵ Only one of the three conditions that he cites allow the denominator of his equation (4) to be negative. Moreover, contrary to Nelson's claim, if the j th cost function is the one that is concave in z , it is not sufficient that $\partial^2 C^j / \partial z^j \partial z^j$ be smaller in absolute value than all other such second derivatives to satisfy the SOC's; in fact, its absolute value must be smaller than that when more than two outputs are involved and must decline as the number of outputs increases.

⁶ This is not the only perverse result that one gets when quasiconcavity is abandoned. For instance, although the SOC's allow only one of the individual cost functions to be concave in the fixed input, when this happens it can be shown that the joint cost function $C(y, w, z)$ will be concave in z , despite the fact that $(n - 1)$ individual cost functions are convex in the fixed input!

⁷ Hicks pointed out that it is quite possible that some inputs may be inferior (regressive) because they are better suited for lower levels of production. However, this situation seems unlikely when inputs are aggregated in broad categories such as land, labor, capital, and materials. Because aggregation is typically justified by assuming that input groups are homothetically separable, in this case inputs must be normal within groups as well to guarantee consistent aggregation (expansion paths are straight lines under homotheticity).

Elasticities in AIDS Models: A Clarification and Extension

Richard Green and Julian M. Alston

In a recent paper in this *Journal* (Green and Alston), we showed that the usual formulas for uncompensated price elasticities in the linear approximate almost ideal demand (LA/AIDS) model were incorrect because the Stone's price index (P) is a function of expenditure shares (i.e., $\ln P = \sum_j w_j \ln P_j$). A common approach is to treat expenditure shares as constant parameters in the Stone's index when taking derivatives for elasticities. We developed corrected formulas for uncompensated price elasticities by using derivatives that took into account the effects of price changes on the shares in the price index.

In the process, and as a side-issue, we also noted (p. 443) that the differences in uncompensated elasticities in the literature (η_{ij})

... carry over directly into the computation of compensated elasticities (η_{ij}^*), which are

$$(6) \quad \eta_{ij}^* = \eta_{ij} + w_j (1 + \beta_i/w_i).$$

In making this assertion, we used the usual Slutsky equation in elasticity form and the usual AIDS income (expenditure) elasticity (i.e., $\eta_i = 1 + \beta_i/w_i$). This procedure is correct only when using the true AIDS model.

In the LA/AIDS model, expenditure elasticities also ought to account for the role of expenditure shares as variables in the Stone's price index. That is, the expenditure shares in the Stone's index are functions of both prices and total expenditures unless preferences are homothetic, and expenditure elasticities will be affected along with the uncompensated elasticities (i.e., $\eta_i \neq 1 + \beta_i/w_i$). In general, therefore, correct compensated elasticities cannot be computed simply by substituting correct uncompensated elasticities into equation (6).

In this note we show correct equations for both (a) expenditure elasticities when the LA/AIDS is estimated and (b) compensated price elasticities incorporating those corrected expenditure elasticities.

Richard Green and Julian M. Alston are a professor and an associate professor, respectively, in the Department of Agricultural Economics, University of California, Davis. Senior authorship is not assigned.

Giannini Foundation Paper No. 957.

The authors thank Jim Chalfant and Richard Gray for having pointed out the problem in our previous paper, leading to the present effort. We also thank Giancarlo Moschini and Mike Wohlgemant who offered some additional insights.

Consider the share equation for the LA/AIDS model using our previous notation (Green and Alston):

$$(1) \quad w_i = \alpha_i + \sum_j \gamma_{ij} \ln P_j + \beta_i \ln (X/P).$$

The general expression for the income (expenditure) elasticity in this equation is

$$(2) \quad \eta_{i,x} = d \ln Q_i / d \ln X = 1 + (dw_i / d \ln X) / w_i.$$

The usual approach treats shares as fixed parameters in the Stone's price index (P) and obtains

$$(3) \quad dw_i / d \ln X = \beta_i \text{ and } \eta_{i,x} = 1 + \beta_i / w_i.$$

That is the result used in equation (6) by Green and Alston. More generally,

$$(4) \quad dw_i / d \ln X = \beta_i [1 - d \ln P / d \ln X], \text{ and}$$

$$(5) \quad d \ln P / d \ln X = \sum_j \ln P_j (dw_j / d \ln X) \\ = \sum_j w_j \ln P_j (\eta_{j,x} - 1).$$

Combining equations (4) and (5) gives

$$(6) \quad dw_i / d \ln X = \beta_i [1 - \sum_j w_j \ln P_j (\eta_{j,x} - 1)].$$

Substituting (6) into (2) gives

$$(7) \quad \eta_{i,x} = 1 + (\beta_i / w_i) [1 - \sum_j w_j \ln P_j (\eta_{j,x} - 1)] \text{ or}$$

$$(8) \quad \eta_{i,x} - 1 = (\beta_i / w_i) [1 - \sum_j w_j \ln P_j (\eta_{j,x} - 1)].$$

Following the approach we used for uncompensated price elasticities (Green and Alston), we can solve the system of simultaneous equations in (8) for the elasticities of interest by expressing the equations in matrix form as

$$(9) \quad M = B - BCM,$$

where M is an n -vector with elements $m_i = \eta_{i,x} - 1$, B is an n -vector with elements $b_i = \beta_i / w_i$, and C' is an n -vector with elements $c_j = w_j \ln P_j$. Then, rearranging terms gives

$$(10) \quad M + BCM = (I + BC)M = B.$$

Premultiplying both sides of (10) by $(I + BC)^{-1}$ gives

$$(11) \quad M = (I + BC)^{-1} B.$$

The elements in M are $m_i = \eta_{i,x} - 1$ so we can obtain the expenditure elasticities by adding 1 to each element of M :

$$(12) \quad N = M + \iota = (I + BC)^{-1} B + \iota,$$

where N is an n -vector of expenditure elasticities of demand ($n_i = \eta_{i,x}$), and ι is a unit vector of length n .

Recall the solution for the uncompensated elasticities of demand in the LA/AIDS (Green and Alston, p. 443) is

$$(13) \quad E = [I + BC]^{-1}[A + I] - I,$$

where A is an $n \times n$ matrix with typical elements $a_{ij} = -\delta_{ij} + [\gamma_{ij} - \beta_i w_j]/w_i$ (when $\delta_{ij} = 1$ for $i = j$ is the Kronecker delta) and all of the other variables are as defined above.

Using the Slutsky equation we may find the compensated elasticities of demand as

$$\eta_{ij}^* = \eta_{ij} + w_j \eta_{i,x},$$

and the matrix of compensated elasticities is

$$(14) \quad E^* = E + NW',$$

where E^* is an $n \times n$ matrix with typical elements η_{ij}^* , and W is an n -vector of shares, w_i . Substituting (12) and (13) into (14) yields

$$(15) \quad E^* = [I + BC]^{-1}[A + I] - I + [(I + BC)^{-1}B + \iota]W' \\ = [I + BC]^{-1}[A + I + BW'] - I + \iota W'.$$

Recall that the typical element in A is defined as $a_{ij} = -\delta_{ij} + [\gamma_{ij} - \beta_i w_j]/w_i$. Further, the typical element in I is $+\delta_{ij}$ and the typical element in BW' is given by $(\beta_i/w_i)w_j$. Thus, the term $[A + I + BW']$ reduces to Γ in which the typical element is γ_{ij}/w_i and equation (15) becomes

$$(16) \quad E^* = [I + BC]^{-1}\Gamma - I + \iota W'.$$

To check these manipulations, consider the case when preferences are homothetic (i.e., $\beta_i = 0 \forall i$ or $B = O$, where O is a zero vector). In this case, all of the income elasticities of demand are 1 and this is verified as $N = \iota$ when $B = 0$ in equation (12). In this case ($B = 0$) equation (16) simplifies to

$$(17) \quad E^* = -I + \Gamma + \iota W',$$

and the typical element is

$$\eta_{ij}^* = -\delta_{ij} + (\gamma_{ij}/w_i) + w_j.$$

This last expression is the usual equation for compensated elasticities (as used by Chalfant, for example). The corresponding formula for the elasticities of substitution is

$$(18) \quad \sigma_{ij} = \eta_{ij}^*/w_j = [\gamma_{ij}/w_i w_j] + 1 \quad (i \neq j).$$

Equations (17) and (18) are special cases; in general, they will be incorrect for measuring compensated price responses.

A more general check of equation (16) using homogeneity conditions was suggested to us by Giancarlo Moschini (Iowa State University 1990) in a personal communication. Homogeneity implies $\sum_j \eta_{ij}^* = 0$ or $E^* \iota = O$. We can see that equation (16) satisfies this condition by noting that $\iota W' \iota = I \iota$, and $\Gamma \iota = 0$ when $\sum_j \gamma_{ij} = 0$.¹

In summary, we have extended our results for uncompensated elasticities in the LA/AIDS (Green and Alston) to show corrected formulas for expenditure elasticities and compensated price elasticities that account for the endogenous nature of expenditure shares in the Stone's price index. Equation (7) is the correct equation for LA/AIDS expenditure elasticities. Equation (16) is the correct formula for compensated price elasticities.² Green and Alston's equation (6) is correct for compensated price elasticities of demand only when preferences are homothetic. We regret any confusion we may have caused.

¹ Moschini also pointed out another implication of homogeneity. In model (ii) of our earlier paper, the elasticity formula (as used by Eales and Unnevehr, for example) was: $\eta_{ij} = -\delta_{ij} + \gamma_{ij}/w_i$. Homogeneity implies that the Marshallian own-price and cross-price elasticities and the income elasticity sum to zero (i.e., $\sum_j \eta_{ij} = -\eta_{i,x}$), and in the Eales and Unnevehr formula this requires that all income elasticities are unitary ($\eta_{i,x} = 1 \forall i$). Thus, only under homotheticity will the Eales and Unnevehr formula give elasticities that satisfy the homogeneity property, and this accounts for the poor performance of that formula in the empirical results we reported in table 2 since the model we used was not homothetic.

² A referee has pointed out that the corrections to the formulas for calculating compensated elasticities may be unimportant for highly disaggregated commodities for which expenditure shares are so small that compensated elasticities are approximately equal to uncompensated elasticities.

Emerging Issues in the Allocation of Public Agricultural Research Funds

George B. Frisvold

The public and private sectors invest more than \$4 billion in agricultural production research and development (R&D) annually. Adjusting for inflation, the average annual rate of growth of R&D investment has been about 2% since 1970. Federal funding of agricultural research has grown at a considerably slower rate than state and private funding. Thus, the federal government's share of total R&D investment has fallen from 27% to 21% between 1970 and 1987.

At the same time, the traditional emphasis of the public research system on farm-level, production-oriented research has been increasingly challenged on different fronts. The increase in commodity program costs resulting from technical change is receiving greater attention (Alston, Edwards, and Freebairn; Oehmke) as the proportion of net farm income coming from government payments has risen from less than 10% in the 1950s to over 30% in the late 1980s. Representatives from the food industry have called for greater emphasis on post-harvest technologies (Wilcke and Williamson). Over two-thirds of each consumer dollar spent on food goes to the processing and distribution stages of production. Hence, it is argued, greater scope for reducing consumer food costs lies in post-harvest innovations. There is also increased public concern over non-price aspects of food production, particularly issues of environmental pollution, food safety, and nutrition. These concerns imply that demand-side impacts of new technologies are potentially very important.

The public research system faces the following dilemma. On one hand, its constituency has

broadened to include food processors and distributors, input suppliers, and environmental and consumer advocacy groups. On the other hand, fiscal constraints limit the federal government's ability to respond to the demands of its expanded constituency. Consequently, the private sector and state agricultural experiment stations (SAES) will play greater roles in determining the rate and direction of technological change.

These developments raise policy questions regarding the relationship between public research institutions and private industry. For example, to what extent should the public sector cooperate or compete with the private sector in research and product development activities? A related issue is the determination of the optimal mix of basic and applied public research. Another set of policy issues involves consideration of demand-side impacts of new technologies and the coordination of research priorities with other agricultural policy goals. This paper examines these policy issues and addresses their implications for economic analysis of the agricultural research system. A major theme of the paper is the potential for applying theories of industrial organization to address agricultural technology policy questions.

Basic versus Applied Research

Currently, the U.S. Department of Agriculture (USDA) and the SAES allocate approximately 40% of their funds to basic (as opposed to applied) research (Langston). The private sector allocates only about 10% of its research expenditures to basic research (Wilcke and Williamson). Basic research includes attempts to improve basic scientific knowledge without the immediate goal of developing a product for market. Basic research results generally come in

The author is an agricultural economist with the Economic Research Service, U.S. Department of Agriculture.

The opinions expressed are those of the author and are not intended to reflect those of the Economic Research Service, U.S. Department of Agriculture.

the form of new information rather than new commercial products, making it more difficult for researchers to prevent others from imitating or using new discoveries. Basic research results from the public sector can be readily borrowed by the private sector to use in commercial product development. Hence, public basic research acts as a subsidy to the private sector. The applied research and product development by public research institutions directly competes with, rather than complements, private industry. Public applied R&D is also devoted to areas such as disease control for specialty crops or pollution abatement technologies which may be socially desirable but not profitable to develop commercially. An important problem for the public research system is to determine the desirable mix of basic and applied research that avoids duplication of private activities and provides socially beneficial technologies not developed by private industry.

A recent paper by Frisvold models the specific choice of allocating research funds between commodities and between basic and applied research as a simplified portfolio-choice model. An experiment station is assumed to face infinitely elastic input and output markets and must allocate a fixed research budget between two commodities to maximize farm income. For simplicity, two periods are assumed: the present, period 0, and the future, period 1. The agricultural sector's expected future technology in period 1 is characterized by a generalized profit function:

$$(1) \quad \pi = \beta_{11}P_{11} + \beta_{21}P_{21} + f(P_{11}, P_{21}, W_1),$$

where π is discounted profits, P_{11} and P_{21} are the expected prices of the two commodities in period 1, W_1 is a vector of expected input prices, and the function f is nondecreasing in expected output prices and nonincreasing in input prices. The terms β_{11} and β_{21} represent the intercepts of the supply functions for commodities one and two, respectively. Following Binswanger, the β_{i1} terms are functions of the station's research activities such that $\beta_{i1} = \beta_{i1}(R_{i1})$ and $\beta_{i1}' > 0$, where R_{i1} is the future stock of research knowledge. The future research stock is itself a function of current research activities:

$$(2) \quad R_{i1} = R_{i0} (1 - \delta_i) + g_i(R_{i0}, A_{i0}, B_{i0}, I_{i0}); i = 1, 2,$$

where R_{i0} is the current research stock, δ_i is the rate of depreciation, g_i is a concave function, A_{i0} is public applied research expenditures, B_{i0} is

public basic research expenditures, and I_{i0} is the expected level of investment in applied research and product development by private industry. The research station's optimization problem is to maximize π with respect to A_{i0} , A_{20} , B_{i0} , B_{20} given the research budget and its expectations of private investment behavior and future prices. The designation of commodity-specific basic research is justified if the commodity groups are at a high level of aggregation, such as crops and livestock. It is assumed further that basic public research is a complement to both private and public applied research in production of the knowledge stock, while public and private applied research are substitutes. The expected level of private investment in each commodity area is exogenously given. The station must not only allocate research between commodities but also must determine the optimal mix of basic and applied research.

The model yields the following comparative statics results. For commodity i , the optimal ratio of basic to applied research is higher: (a) the greater the level of private investment in commodity i research, (b) the lower the total public research budget, and (c) the lower the initial stock of knowledge in the commodity area. Conversely, a shift to greater emphasis on applied research in commodity area i is warranted: (a) if the private sector does not invest in that area, (b) if commodity i requires high levels of maintenance research (i.e., δ_i is large), and (c) as the price of commodity i increases.

This simplified model makes two very restrictive assumptions. First, the public and private sectors are working to achieve the same types of technological changes at the farm level. Second, no market distortions or environmental externalities are present. Optimal government response to private sector R&D investment, in general, will be highly sensitive to these assumptions. To illustrate, consider a more complete public research objective function, U of the form

$$U = \lambda_f \pi_f + \lambda_i \pi_i + \lambda_p \pi_p + \lambda_c CS - \lambda_g GP - \lambda_e ED - \lambda_r RC,$$

where π_f is farm profits, π_i is input supplier profits, π_p is processor/distributor profits, CS is consumer surplus, GP are government commodity program payments, ED is a dollar value of environmental damage from agricultural production, RC is research costs, and the λ terms are weighting parameters representing distributional preferences of the government toward af-

affected groups. If the government wanted to maximize economic efficiency (given programs), it would equate all λ values. Virtually all private research is carried out by either the input or food industries. Their objectives, rationally, would be to maximize π_i and π_f , respectively. These objectives are not likely to coincide with a government objective, which includes consideration of program and environmental costs of technological change. For example, a significant portion of private R&D is pesticide research for commodity program crops. A government objective function with positive values for λ_g and λ_e would be less likely to complement this research emphasis.

Private industry representatives have argued that the public sector should alter its research emphasis toward more basic research which complements the research activities of post-harvest industries (Wilcke and Williamson). Because the post-harvest phase of production is the area of greatest value added, it is also the area of greatest potential food cost reductions. However, technological change that has the highest payoff to food producers and distributors will not necessarily have the highest benefits to farmers or society in general. Various authors (Alston and Scobie; Freebairn, Davis, and Edwards; Holloway) have demonstrated that it is even possible for post-harvest technological change to reduce farm-level income. These results show that the interests of producers at different stages of the production chain do not always coincide. Thus, the degree to which public institutions will (or should) complement private research agendas depends on how closely those agendas coincide with the preference function, U .

The divergence of interest between the public sector and various agents in the private sector has important implications for assessment of joint public-private research funding. Private grants to state experiment stations represent only about 6% of their total budgets (CSRS). However, a large part of these total budgets are salaries and administrative costs which are relatively independent of the type of research conducted. Private grants, therefore, comprise a more significant portion of a station's discretionary spending. In a case study of Canadian barley research, Ulrich, Furtan, and Schmitz found evidence that private grants from brewers biased the direction of research in their favor and away from the social optimum. Although the social gains from the joint research project were positive, there was

a large public opportunity cost of private influence in the direction of research.

Public and Private Competition

The classic example of direct competition between public research institutions and the private sector has been the seed industry. Public varietal development and releases have been credited with acting as a disciplining device to maintain a relatively competitive structure within the industry. There is growing concern, however, that plant patenting by public research institutions will have a number of detrimental effects. A major argument is that gains from patenting will induce public research systems to behave as profit-maximizing firms rather than social welfare-maximizing ones. Recent literature on the theory of the public firm (De Fraja and Delbono; Cremer, Marchand, and Thisse) calls into question the basic assumption that profit maximization by public firms is suboptimal, however. De Fraja and Delbono use a game-theoretic approach to examine an industry comprised of a public firm and several private, oligopolistic firms. They derive a Nash equilibrium where social welfare is higher when the public firm's goal is profit rather than social welfare maximization. Such a result may or may not apply to experiment stations competing with private seed companies. The point to be made, however, is that new models of optimal public firm behavior may be employed to rigorously evaluate public research strategies.

Product versus Process Research

Cost reduction at the farm level is not always the primary objective of agricultural research. Product quality-enhancing research often affects farm operators more on the demand side of the equation than the supply side. Demand-creating research may be aimed at creating new products or market niches such as those for lower fat or cholesterol foods. Certain new products are not less costly to produce but count on capturing premiums for perceived desirable environmental or health attributes. Examples would be organic produce or "dolphin safe" tuna. Demand-creating research would also include the development of alternative uses for agricultural products or improvement in product desirability to processors or foreign consumers. Other research at-

tempts to alter the maturation date of produce to better take advantage of seasonal price increases. Butler, Carter, and Zepeda's recent study of farmer perceptions of bovine somatotropin also illustrates that farmer technology adoption decisions are increasingly affected by considerations of food safety and consumer acceptance.

Demand-creating R&D may be modeled as an improvement in the average quality of an existing product which increases consumers' willingness to pay for it (Levin and Reiss). Figure 1 demonstrates the welfare effects of an increase in product quality which induces a shift in the demand curve from D to D' . As consumer willingness to pay for the product increases, the equilibrium price rises from P to P' . Producer surplus is increased by the area $PABP'$, while consumer surplus increases by the area $CBP'DAP$. The total gross benefits to product quality improvement is equal to the area $ABCD$.

Government intervention in commodity markets can have important effects on the gains from demand-creating research. Consider the effects of a target price/deficiency payment scheme shown in figure 2. Initially, the target price is set at T , the market price is P , output is Q , government deficiency payments equal the area $TACP$, consumer surplus equals the area PCF , and producer surplus equals the area TAP . An outward shift of the demand curve from D to D' could represent the impact of a technological breakthrough in ethanol production on the demand for corn. In this case, the demand shift has no effect on output, producer surplus, or consumer surplus. The improvement in demand does, however, reduce government payments to

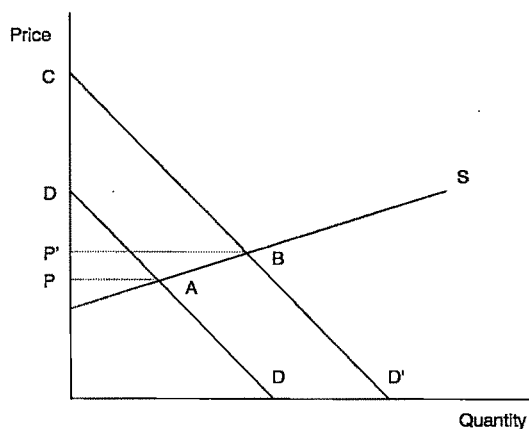

Figure 1. Effects of improved product quality

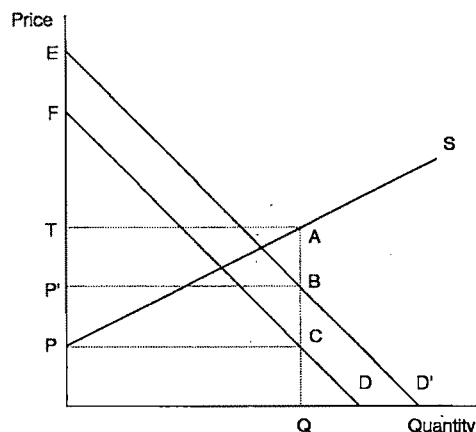

Figure 2. Effect of demand-creating research on a market under a target price/deficiency payment scheme

$TABP'$. Producers have no incentive to fund such demand-creating research because it would only change the proportion of their income coming from the market as opposed to that coming from the government, leaving total returns unchanged.

Three important points can be made here. First, demand-creating innovations can reduce the social costs of farm income support policies. In contrast, cost-reducing innovations increase the cost of target price programs. Second, target price schemes can make demand-creating innovations less attractive to producers than cost-reducing innovations. Finally, to the extent that consumers are also taxpayers, they may benefit more from demand-creating innovations, which reduce the tax burden of income support programs, than from cost-reducing innovations, which lower food costs but raise their tax burden.

Product quality research is complicated by problems of imperfect information. Many quality characteristics consumers care about, such as flavor, are not readily observable at the time of purchase. Consequently, consumers use appearance as a signal of underlying product quality. The signal value to consumers of product appearance (and hence the premium they are willing to pay) depends on the degree of correlation between appearance and unobserved quality.

A recent paper by Frisvold and Putler examines the welfare effects of research on product attributes in the context of asymmetric information concerning the relationship between

unobserved product quality and appearance. Consumers select a product given its price and expected quality given its appearance, updating their expectations of the quality-appearance correlation given new information. The producer side represents an experiment station or marketing order that invests in research to alter product appearance and/or unobserved quality to maximize net producer returns to research. Researchers face the following intertemporal tradeoff. In the short run, there are gains from altering product appearance only, while the gains from improving average quality accrue only in the long run. Reducing the appearance-quality correlation, however, erodes the signal value of appearance over time. Examples of such "signal jamming" effects have been observed in the markets for tomatoes and stone fruits.

The imperfect information equilibrium is characterized by overinvestment in appearance and underinvestment in quality relative to the social optimum. A net social loss from research is possible such that surplus is simply transferred from consumers to producers while research expenditures represent a type of dead-weight loss. Key variables driving model results are consumers' marginal utility with respect to quality, researcher and consumer expectation formation, and the researcher's discount rate. The model has two major implications for grading standards. First, grading standards based on appearance alone can have negative long-run welfare effects. Second, there are potential gains from improved grading/labelling based on quality which is unobservable to consumers. Such standards not only reduce consumer uncertainty but can create research incentives more compatible with the socially optimal path of technological change.

Conclusion: Future Areas of Research

Historically, major technological breakthroughs have come from publicly funded research on farm-level innovations. In the future, such breakthroughs are more likely to come from privately funded research on post-harvest innovations. As a consequence, traditional methods of analyzing the impact of public research in terms of simple supply shifts while ignoring private sector behavior will prove increasingly inadequate. Industrial organization theories of imperfect and non-price competition, the public firm,

and asymmetric information can play an important role in addressing emerging policy issues in agricultural research.

The refinement and empirical application of these theories to agriculture implies a need for much better information on private R&D activities. Such data are vital in assessing the impact of government policies toward basic research, scientific education, intellectual property rights, antitrust policy, and investment tax credits on the extent and direction of private innovation. Greater knowledge of private R&D trends is essential if the public sector wishes to reduce redundancy in research and to allocate funds to higher payoff investments. Ironically, the availability and quality of private R&D data appears to be declining. Unless institutional innovations are forthcoming that reverse this growing information deficit, policy makers will be less able to identify those factors that retard or promote technological change.

Finally, there is a need for more empirical analysis of the behavior of public research institutions. Two possible areas of inquiry include patenting by public institutions and joint public-private research ventures. A positive theory of government behavior is necessary for a complete understanding of the process and direction of technical change. Revealed preference estimation of government technology policy may also be a fruitful avenue of research.

Plant Variety Protection, Private Funding, and Public Sector Research Priorities

Mary K. Knudson and Carl E. Pray

The objective of the Plant Variety Protection Act of 1970 (PVPA) was to increase a firm's ability to capture the returns on its applied breeding research and development (R&D) investments. Firms were expected to increase their R&D investments to take advantage of increased returns. Studies have shown that the PVPA has induced the private sector to increase its investments, particularly in soybeans and wheat (Butler and Marion; Perrin, Kunnings, and Ihnen). Recently, Stallman raised the concern that the PVPA may also influence agricultural experiment stations (SAES). She suggests that public R&D priorities may be shifted away from commodities and research topics that have high social rates of return.

While it is possible that the PVPA will pull research away from the socially optimal allocation of resources, other sources of distortion may be equally important. Political pressure on public research or industry's contributions to public research may lead to too much research on certain topics (Ulrich, Furtan, and Schmitz) or commodities. Another concern is that, in certain commodities, the private sector research is crowding out public research. Both concerns raise the questions of who will teach the next generation of scientists, who will provide varieties when markets are insufficient to induce private research, and who will maintain the competitive structure of agricultural production, inputs, and marketing.

This paper is part of a larger project on the impact of the PVPA and patents on public and private R&D, and on crop yields and genetic

diversity of major field crops in the United States. The primary purpose of this paper is to measure the PVPA's impact on public sector plant breeding. The secondary purpose is to find out whether industry directly influences public research. As a preliminary study, we examine public sector R&D expenditure patterns on wheat, soybeans, corn, cotton, and sorghum.

Public Sector Resource Allocation and Intellectual Property Rights

Table 1 shows why some people are concerned. Since 1980 the number of scientists years (SYs) in some of the Agricultural Research Service (ARS) and SAES plant breeding programs have declined. In corn, SYs dropped 22%, the most of the five crops. However, crowding out is most likely to occur in corn because corn attracts more private resources and is growing at a faster rate than the other four crops. Sorghum, too, has a long history of private research and experienced a decline in public sector SYs. In contrast public SYs have increased in soybeans and wheat, which is where the PVPA strengthened property rights the most. Cotton is an anomaly; it declined even though the PVPA strengthened SAES' ability to appropriate gains.

Table 2 shows that SAES have been acquiring Plant Variety Protection Certificates (PVPCs). SAES started applying for wheat, soybean, and cotton PVPCs in 1970. The first two columns in table 2 show that the public sector acquired the greatest number of PVPCs in soybeans and wheat. No PVPCs were issued for corn or sorghum inbred lines even though these crops were eligible for protection.

The second half of table 2 shows the results of a 1989 ARS survey of SAES on their use and future intentions to use PVPCs and utility patents (UPs). Two-thirds of the SAES currently use PVPCs, but only two more plan to use them

Mary K. Knudson is a visiting assistant professor in the Institute of Public Policy Studies at the University of Michigan. Carl E. Pray is an associate professor in the Department of Agricultural Economics, Rutgers University. Authorship is shared equally.

^b The number of AES that stated that future use of plant protection was either definite or probable.

in the future. The number of SAES that plan to use UPs will almost double from nineteen to thirty-seven. The number of SAES using PVPCs and UPs for the major field crops, particularly corn, sorghum, and wheat, will grow more rapidly than the totals. At present only a few experiment stations use UPs on these crops.

Model of Public Research Resource Allocation

Most economists advise government research administrators to allocate their research resources to maximize expected social benefits from research. But most empirical studies of research resource allocation in the agricultural economics literature assume that research administrators are also influenced by the demands of organized interest groups (Huffman and Miranowski, Hayami and Ruttan, Rose-Ackerman and Evenson). These models assume that research administrators are cost minimizers within a budget that is partly determined by interest groups and politicians's demand for research.

An alternative way to model the supply side is to consider ARS and SAES administrators as

budget-maximizing bureaucrats (Ruttan). The director invests his research resources in different commodities to increase his research resources in the future. Major sources of funding are state and federal governments, private industry and royalties from PVPCs and UPs. Under this scenario, for each funding source, administrators will like to increase its research contributions. Because the funding sources vary with regard to their own research objectives, the strategies that the administrator employs to gain this increase will vary depending on the funding source.

To increase state and federal contributions, the ARS and SAESs could either develop technologies that reduce farm production costs or that increase consumer welfare and the income of influential farmers and agribusiness. Thus, the director would want to maximize total social benefits. Measurements of recent research productivity and possible social benefits from this research could help determine where these benefits would be highest. In addition, the director might reduce expenditures in commodities where private sector research is strong because social benefits from duplicating private research would be limited.

Research directors would probably take a different approach to increase industry's contributions. For example, the ARS and SAESs could concentrate on research that increases the profits of agribusiness and commodity groups. More immediate increases might come if the public sector shifted resources onto topics which the private sector already helps fund.

Since the passage of PVPA, public research institutions, along with firms, can collect royalties from sales of pure line varieties of sexually propagated crops. To take further advantage of income from royalties, the ARS and SAESs may seek more market space by developing superior varieties to those that the private sector produces.

In our model, ARS and SAES administrators will consider social benefits from research, contributions from industry, and royalties from PVPCs and UPs when allocating research resources among commodities. More formally, this relationship can be written as

$$(1) \quad RD_{ij} = f(SB_{ij}, NPR_{ij}, IND_{ij}, PRIV_{ij}, RP_{ij}),$$

where RD is ARS and SAES expenditure at time i on crop j , SB is the expected social benefit from research, NPR is expected royalty income to SAES from research, IND is industry's funding of public research, $PRIV$ is the quantity of private research, and RP is a measure of public research productivity.

The actual variables used and sources of data are shown in table 3. However, some of the independent variables need further explanation. One common way of measuring social benefits is net social surplus (NSS) (Perrin and Foster):

$$(2) \quad NSS_j = c * k_j * V_j * [1 + k/(2/n_j + 2/e_j)] - C_j(k),$$

where for every crop j , c is a capitalization factor (which captures the present value of social benefits), V is the value of production, k is the percent reduction in production costs resulting from a new technology, e is the elasticity of supply, n is the absolute value of the elasticity of demand, and C is R&D costs. We assume that c is the same for all crops, so $c = 1$. For simplicity, we also assume that the reduction in production costs is 1% for all five crops, so $k = 1$. Therefore, equation (2) becomes

$$(3) \quad SB_j = V_j * [1 + 1/(2/n_j + 2/e_j)] - C_j,$$

which we use to estimate SB_{ij} . Several different lag structures on the value of production were used in estimating SB_{ij} . However, an average over the previous five years proved to be the best lag.

Experiment station directors might also look at measures of the productivity of research programs other than k such as numbers of varieties released or publications. We tried as a rough measure of research productivity (RP) the number of varieties released divided by earlier research expenditure. The coefficients for all variables, with the exception of $PRIV$, are expected to be positive.

Empirical Results

Three specifications of our model [equation (1)] were estimated in linear form using OLS. Several functional forms of our model were estimated, but the linear form had the best fit. The results of the linear specifications are shown in table 4. Social benefits (SB) are consistently positive and significant at the 5% or 10% level across all three specifications. Research produc-

Table 3. Variables and Data Source

Variables	Description and Data Source
Dependent variables	
<i>RD</i>	Federal and SAES R&D plant breeding and maintenance (RPAs 307 and 405) from CRIS data in time periods 1968, 1972, 1976, 1980, 1984, and 1988 and crops corn, wheat, soybeans, cotton, and sorghum.
Expected social benefits	
<i>SB</i>	Producer and consumer benefit calculated using Perrin and Foster (see text).
<i>RP</i>	Productivity of research for i less than 1980 is the number of varieties for each j released in <i>Crop Science</i> 1968–70 divided by the number of SYs in 1968. For i greater than or equal to 1980, the number of varieties for each j from 1985–87 was divided by the number of scientific years in 1985.
<i>PRIV</i>	Private expenditure on research from Perrin, Kunnings, and Ihnen; and Kalton, Richardson, and Frey. This variable was lagged in the following manner: for 1968, 1972, 1976, 1980, 1984, and 1988; private expenditures were taken from 1960, 1965, 1970, 1975, 1980, and 1982, respectively.
SAES income generation	
<i>NPR</i>	Dummy for the PVPA is one for the self-pollinated crops in which SAES took PVPCs—wheat, soybeans, and cotton—after 1970.
<i>IND</i>	Industrial funding per crop per year from CRIS data.

Table 4. Factors Influencing Public Allocation of R&D Resources: Regression Results

Dependent Variable: Applied Public R&D by Commodity			
Independent Variables	Specifications		
	1	2	3
Social benefits (<i>SB</i>)	0.00011 (1.64)	0.00034 (6.884)	0.00013 (1.91)
Research productivity (<i>PROD</i>)	-0.00003 (-.059)	0.0004 (.740)	0.00011 (0.25)
Private research (<i>PRIV</i>)	-0.030 (-.93)

Industry contributions (<i>IND</i>)	6.40 (4.93)		5.22 (3.91)
Constant	0.0009 (2.04)	0.0003 (.500)	0.0006 (1.07)
Adjusted R^2	.828	.648	.77
Degrees of freedom	25	26	25

tivity (*RP*) changes signs and is not significantly different from zero in any specification. Private research (*PRIV*) has the expected sign but is not significant. However, this relationship deserves a more in-depth examination which is beyond the scope of this paper. The intellectual property rights coefficient (*NPR*) is positive in most specifications but is statistically significant only in specification 2. When the industry contributions variable (*IND*) is added (specification 3) the R^2 increased, the *NPR* coefficient remained positive but was no longer significant, and the *RP* coefficient changed to the expected sign. *IND* is positive and significant in all specifications of the model.

The regression results support the argument that expected social benefits guide research directors in their allocation of resources. They also suggest that intellectual property rights have influenced the commodity composition of public research. They do not support the argument that research contributions by industry and commodity groups induce directors to allocate more government resources to those commodities. The industry variable is positive, but the elasticity of public research with respect to industry contributions to public research is less than one (.5 to .6, depending on the specification). This result indicates that public research administrators substitute private contributions for public research dollars rather than spending more public research dollars to capture limited industry contributions, as some critics predicted.

Conclusions

The regression results indicate that social benefits are important in influencing the direction

of research. There is some support for the argument that the new opportunities for income provided by the PVPA have influenced the direction of public research. The key policy question, however, is whether PVPA and industry contributions would result in lower social benefits.

The first column in table 5 shows the most recent (1988) allocation of public resources between the five crops in this study. If in the future resources are allocated to crops in which property rights have been improved, wheat, cotton, and soybeans would receive more resources. If public resources were allocated by the value of the seed market, they would be allocated like column 2. The share of corn would more than double, wheat's share would be cut in half, and cotton's share would decline from 14% to 3%. If resources are allocated more like contributions of private companies and commodity groups (column 3), the corn and soybeans will increase while the other crops' shares will decline. If the public sector tries to duplicate the private sector (column 4), even more emphasis would be placed on corn.

Would reallocating the public sector resources according to the value of the seed market reduce social benefits? A definitive answer is not possible here. However, if resources were allocated according to our crude measure of social benefits, they would resemble column 5. This column suggests that public resources would shift away from wheat and cotton toward corn. Thus, if experiment stations shifted resources in the direction suggested by industry's contribution, they would also be moving toward an allocation of resources that would increase social benefits. If they allocate resources according to the value

Table 5. Current and Potential Future Allocation of Research Resources—Selected Crops (percent of 5-crop total)

	Current (1988) Public Allocation	Allocation Based on Seed Market	Industry Contribution	Private R&D 1989	Allocation Based on SB
Corn	25	58	34	68	40
Sorghum	8	6	6	6	4
Wheat	30	12	19	7	18
Cotton	14	3	11	3	9
Soybeans	24	21	29	16	29

Inventions Intended for Use in Agriculture and Related Industries: International Comparisons

Robert E. Evenson

Private firms invest substantial funds in research and development (R&D) to discover and develop inventions intended for use by crop and livestock farmers.¹ Most of these inventions are granted patent protection, and many inventors obtain patent protection in more than one country for their inventions. Publicly supported agricultural R&D, including research done in the U.S. Department of Agriculture-State Agricultural Experiment Station (USDA-SAES) system, also produces inventions intended for use by farmers, but few of these inventions are granted patent protection.²

A recently completed research project conducted at Yale University provides procedures for assigning patented inventions to "Industries of Use" (IOUs) including agricultural production industries.³ Specifically, the project developed a "concordance" mapping inventions classified by International Patent Class (IPC) into industries classified by Standard Industrial Class (SIC). The concordance can be applied to international patent data sets reporting IPCs and thus provides estimates of inventions by IOU (or by Industries of Manufacture, IOM) by country of origin.⁴ This paper reports estimates of inventions intended for use in U.S. agricultural production sectors as well as in the input supply and agricultural service sectors. Data for Great

Britain, France, and Germany are utilized for international comparisons and for estimates of technology flows between countries.

Part 1 discusses the concordance methodology. The second part reports estimates of inventions by two- and three-digit industries of use. The third section reports international comparisons.

The Yale-Canada Concordance

The concordance utilizes data from the Canadian Patent Office to compute probability distributions mapping inventions from an International Patent Class to two-, three-, or four-digit SIC Industries of Manufacture and Industries of Use.⁵

The Canadian Patent Office has been assigning an IPC, an IOM, and an IOU to each patent granted since 1978 (to Canadian origin patents since 1972). (See Ellis for a full discussion.) This provides a large data base (more than 200,000 patents) for an international sample of inventions (only 12% of Canadian patents are of Canadian origin, nearly half are granted to U.S. inventors). The IPC structure is very detailed, with roughly 100,000 classes. (The actual concordance is based on a more aggregate set of 6,000 classes.) The procedure to estimate the concordance is to compute the distribution across IOMs or IOUs for each detailed IPC for the Canadian sample. The reliability of this concordance, when applied to other patent data sets (e.g., for the U.S.) depends on the inherent "diffuseness" or matching of IPCs with IOUs or IOMs and/or possible changes in industry mixes. Tests of reliability (Kortum and Putnam) of the concordance showed that the concordance was

Robert E. Evenson is a professor, Economic Growth Center, Yale University.

¹ Evenson and Huffman, report estimates of R&D expenditure by private firms in the U.S. farm implements industry of \$592 million in 1984 and of \$837 million by firms in the agricultural chemicals industry.

² See Evenson and Putnam, and Evenson and Huffman for a fuller discussion of protection of USDA-SAES inventions.

³ R&D data are reported by the industrial firms conducting the R&D. One can infer only roughly the industry of use for this R&D and for the associated inventions.

⁴ Evenson and Huffman, chap. 7, and Evenson and Putnam also report data on inventions by technology field for agriculture. They note a growing proportion of inventions granted to foreign investors in all agriculturally related technology fields in recent years.

⁵ See Kortum and Putnam for an extended analysis of the concordance and an alternative concordance.

very reliable at the two-digit level and generally reliable at the three-digit level.⁶

Given the uniqueness of these data, however, it will be useful to generate data for some four-digit sectors and to interpret them in the context of their limited reliability. (Note the estimated series are unbiased estimates of inventions by IOU.) In the sections to follow, estimated series by IOU have been generated from the U.S., U.K., French, and German patent data bases of the European Patent Office (EPO). For the United States, the EPO has assigned IPCs to U.S. patents for the 1920–69 period, and these historical data are summarized in this paper as well.⁷

Inventions by Industry of Use

The Farm Industries

Farms conduct very little R&D, and farmers make few inventions (Evenson and Huffman, chap. 5). Farm industries, however, are the industries

of use for many inventions. During the 1970s more than 900 inventions per year granted patents by the U.S. Patent Office were destined for use in the farm sector. More than 25% of these were “imported” from abroad, i.e., they were invented in other countries.⁸

Table 1 reports an historical summary of inventions intended for use in six three-digit SIC farm industries with details for selected four-digit SIC industries. It should be noted that many inventions assigned to the three-digit class are not further assigned to a four-digit class. Thus, for each four-digit industry, one may view these inventions as specific to the industry in question; but further note that the industry also uses inventions that are specific to the three-digit industry.

The first seven columns in table 1 report historical data for all inventions granted patents in the United States, i.e., including inventions originating in foreign countries (see table 3 for further details on countries of origin). Columns eight and nine report import ratios, i.e., the ratio of imported inventions to domestic inventions, for the 1970s and 1980s. These import

⁶ Tests are made (Kortum and Putnam) using part of the Canadian data to predict distributions for the remaining data. No direct tests of the international applicability of the concordance were made.

⁷ The International Patent Office assigned IPCs to U.S. patents back to 1920, enabling the historical series. The U.S. Patent Office did not make such assignments until 1965.

⁸ Evenson and Huffman report estimates of inventions used in agriculture based on “technology fields.” Their estimates show only one-third as many inventions as reported here.

Table 1. Inventions Used by the U.S. Agricultural Production Sector

	Average Annual Inventions Patented							Import Ratio		Export Ratio 1970s
	1920s	1930s	1940s	1950s	1960s	1970s	1980s	1970s	1980s	
011 Livestock farms (total)	204.4	166.3	96.6	178.3	211.3	230.9	202.3	.21	.40	.42
0111 Dairy farms	25.0	22.5	14.3	21.7	23.8	28.5	23.8	.28	.55	.44
0112 Cattle farms	13.0	10.4	7.6	17.2	23.3	27.8	25.9	.20	.41	.39
0113 Hog farms	6.1	8.5	2.6	8.2	10.9	9.7	10.0	.09	.48	.49
0114 Poultry farms	76.9	54.8	25.4	50.0	44.6	38.9	34.3	.17	.31	.34
0115 Sheep-goat farms	.1	.1	.2	.3	.5	.7	1.0	.90	.13	.03
012 Other animal farms (total)	39.7	23.3	14.2	20.5	19.7	22.6	26.7	.18	.19	.17
0121 Beekeeping farms	13.4	8.9	5.5	7.2	5.4	6.4	10.5	.09	.22	.14
0122 Horse farms	18.2	7.6	3.7	5.6	6.8	8.2	8.4	.26	.14	.11
0123 Fur skins farms	.7	.2	.1	.4	.3	.3	.2	.00	.00	.00
013 Field crop farms (total)	443.6	320.4	227.3	425.7	383.8	406.7	332.0	.26	.47	.58
0131 Wheat farms	32.5	23.8	13.9	23.4	29.0	33.3	29.2	.27	.46	.40
0132 Small grains farms	4.4	5.9	7.0	11.1	15.9	15.3	10.6	.47	.47	.55
0134 Corn farms	8.9	7.3	7.5	11.5	9.9	10.6	9.1	.16	.52	.37
0135 Forage-hay farms	8.8	6.2	6.1	18.1	17.4	15.4	16.7	.26	.58	.59
0137 Tobacco farms	1.0	1.4	1.1	2.0	3.5	3.5	4.6	.13	.78	.58
0138 Potato farms	6.8	4.4	3.3	6.0	3.4	3.6	2.6	.20	.21	.43
015 Fruit and vegetable farms	43.8	37.9	23.1	57.5	68.2	64.9	35.7	.15	.31	.21
016 Horticultural farms (total)	23.0	31.9	16.4	32.6	37.7	56.3	57.1	.21	.33	.28
0161 Mushrooms	1.7	2.8	1.5	4.2	4.6	4.8	4.7	.17	.40	.27
0162 Greenhouse products	6.2	9.2	4.3	6.7	8.1	10.7	11.0	.26	.30	.34
0163 Nursery products	2.2	2.7	1.4	3.4	4.4	7.4	6.2	.21	.27	.25
017 Combination farms	68.1	67.3	57.5	106.5	138.4	142.4	150.2	.35	.60	.60
All farms	824.6	647.1	435.1	819.1	859.1	923.8	804.0	.25	.45	.50

ratios changed dramatically from the 1970s to the 1980s.⁹

The historical series show quite regular patterns. Inventions for all farm sectors (except for horticultural farms) declined during the 1930s and 1940s, then rose sharply in the 1950s, 1960s, and 1970s. Most sectors show a decline in total inventions in the 1980s, and all sectors show a decline in domestic origin inventions in the 1980s. The decade of the 1930s was affected by the Great Depression, and the 1940s were affected by World War II. Most of the inventions destined for use in the farm sectors originate in the industries supplying agriculture (see table 2), and these industries grew in importance in the 1950s and 1960s.

Comparisons across four-digit industries have limited relevance because many inventions can be used in several four-digit industries and hence are assigned only at the three-digit level. Such comparisons are of some interest, however. For example, they show differences in the timing of inventions, e.g., the early boom in poultry inventions in the 1950s and high levels of inventions in the 1980s in specialized animal and nursery farm industries. Comparisons across three-digit industries show that field crop farms have received more inventions than livestock farms.

Returning to the matter of the import ratios, it is clear that these ratios differ between industries, being lowest for livestock, fruit and vegetable, and horticulture farms and highest for field crop farms. These ratios reflect two factors. First, there are fundamental differences in technologies and their transferability. Some inventions are highly location specific and hence worth little in another country. Second, increases in the import ratios from the 1970s to the 1980s indicate that the "competitiveness" of foreign inventors has risen markedly in the 1980s. Not only has the foreign share risen, but domestic invention has declined sharply for most industries (specifically for the field crop farm industries).¹⁰

Table 1 also reports an export ratio, i.e., the ratio of patents granted to U.S. inventors in France, Germany, and the United Kingdom to U.S. domestic patents. This ratio has remained

approximately constant over the 1970s and 1980s. While not fully comparable to the import ratio (which includes patents from all foreign countries), it does show that U.S. inventions have been competitive abroad (see section 3 below for further discussion).¹¹

The Farm Supply Industries

Table 2 reports data comparable to table 1 where the industries of use are the farm supply industries. These industries are the primary sources of inventions for the farm industries. Table 2 is designed to show the flows of inventions to these supplying industries and perhaps to shed some light on the apparent loss of competitiveness of these industries as invention suppliers to the farm industries.

The same general historical patterns exhibited in table 1 appear for the industries in table 2. Inventions used in these industries declined during the 1930s and 1940s and rose over the 1950s, 1960s, and 1970s. Total inventions declined for both the agricultural implements and the agricultural chemicals sector in the 1980s, and the rising import ratios indicate a sharp decline in domestic invention. The 27% decline in inventions of use for the agricultural implements and agricultural chemicals industries from the 1970s to the 1980s was considerably greater than the 15% decline for the farm industries for this period.

The services sector industries are the industries of use of significant numbers of inventions. These industries actually perform many farm functions. As with other sectors these too have experienced increased foreign competitiveness.

International Comparisons

Table 3 reports comparative import and export ratio data for the four major origin countries for agricultural inventions. It also reports invention by source country for the 1969 to 1987 period. These comparisons are reported for the major three-digit industrial sectors of use including crop and livestock farms.

For each industry two further indexes are re-

⁹ Evenson and Huffman report data by technology field, indicating that the import ratio for all agriculturally related inventions rose from less than .2 in the 1920s and 1930s to .4 by the 1950s and approximately .5 by the 1960s and 1970s.

¹⁰ The question of rising competitiveness has substantial policy relevance and requires further extensive analysis. (See Evenson for a further discussion.)

¹¹ These export ratios are sensitive to patent law changes in other countries and require careful interpretation. Except for Japan, however, legal systems in most OECD countries are quite similar. Further, each country's system provides "national treatment" to foreign inventors (Evenson and Putnam).

Table 2. Inventions Used in Industries Supplying U.S. Agriculture

	Average Annual Inventions Patented							Import Ratio		Export Ratio
	1920s	1930s	1940s	1950s	1960s	1970s	1980s	1970s	1980s	1970s
311 Agricultural implements	198.5	154.1	115.4	179.7	186.7	201.4	170.8	.28	.61	.52

571 Farm machinery	.5	.5	.5	.6	1.0	1.2	1.3	.33	.50	.44
501 Farm products	5.8	5.1	3.3	5.5	9.0	7.6	6.7	.18	.30	.29

ported (in parentheses). The first is the total number of domestically produced inventions of use in the four granting countries. The second is the ratio of total patents granted in the four countries to domestically produced inventions in the four countries. This ratio can be regarded to be an index of "transferability" for the technology in question. When this ratio is high, it in-

dicates that inventions originating in one country have a high degree of usefulness in another country.¹²

¹² These ratios have changed from the 1970s to the 1980s. The level of these indexes for 1970 is positively correlated with the change in the import ratios from the 1970s to the 1980s across industries. This suggests that the change in foreign competitiveness is higher in those industries with more inherent transferability.

Table 3. International Comparisons by Industrial Use Field

Granting Country	Trade Ratios		Inventions by Country of Origin						
	Import	Export	U.S.	U.K.	France	Germany	Japan	Canada	Others
A. Crop production (21,251, 1.94)

C. Services to farmers (14,918, 1.58)									
U.S.	.26	.33	6717	270	195	384	292	54	581
U.K.	1.26	.43	988	1863	150	416	164	16	605
France	.99	.24	570	257	2447	649	146	13	788
Germany	.55	.37	668	274	236	3897	193	13	765
D. Agricultural implements (6,219, 1.69)									
U.S.	.41	.47	2518	140	105	304	240	22	223
U.K.	1.43	.65	430	663	105	357	110	14	280
France	1.58	.41	332	129	852	478	81	3	330
Germany	.28	.66	432	159	145	2187	141	4	476
E. Agricultural chemicals (7,462, 2.39)									
U.S.	.66	.51	4011	501	212	789	508	5	636
U.K.	1.98	1.23	866	801	182	540	323	9	476
France	3.13	.71	733	325	477	478	279	8	520
Germany	1.25	.86	930	410	215	2116	382	7	695

The crop production farm sector received considerably more invention attention (2.4 times as much) than the livestock production sector. The services to farmer industries also received a high level of inventions, more than received by the implements and chemical inventions combined.

The transferability indexes indicate that inventions used in the agricultural chemicals industries are most transferable. The lowest levels of transferability (i.e., the most location-specific) are for inventions used in the livestock production industries and in services to farmers.

Table 3 reports import and export ratios for the four major inventing countries. Because the denominator of these ratios is the same, the differences in the ratio is a kind of net trade ratio (note imports from all countries are counted in the import ratio but only exports to the other three countries are counted). The United States, it may be noted, has a favorable ratio of exports to imports relative to other countries except in agricultural implements and to a lesser extent in agricultural chemicals, where Germany has a more favorable ratio.

The country of origin data show that the United States is the leading originator, i.e., domestic producer, of inventions in most industries and that Germany is the second leading originator of inventions. The United States is also the leading "consumer" or user of inventions in all industries.

Concluding Comments

The organization of invention data by IOU has only recently become feasible. This paper reports the first compilation of such data for the agricultural industries. The data series provide both historical and international insights. At this stage the data are intended to be informative indicators. It is expected that further refinement in the data series and methods may be achieved in the future. More important, the reporting of these indicators should provide scholars with inspiration for the further studies required to test hypotheses and to fully develop policy implications.

International Technology Transfer: Private Channels and Public Welfare

Margot Anderson and Bruce A. Larson

The economics of technology transfer is receiving increasing attention as economists acknowledge the role of transfer on future technological innovation, income, and growth. In agricultural economics, much research has focused on improving the international structure of intellectual property to facilitate technology creation and transfer or on analyzing the impacts of new technology, including that acquired from foreign sources, on productivity growth and welfare (Centner and White; Cochrane; Edwards and Freebairn; Alston, Edwards, and Freebairn). In general, this body of research is either not concerned with how technology is transferred or assumes the existence of a poorly defined technology market. But the specific channels of technology transfer are important in many sectors in the economy.

In agriculture, the increasing importance of the private sector in the creation and transfer of technology suggests a closer examination of the channels of transfer.¹ These channels include direct exports of goods that embody technology, foreign direct investment, technology licenses, and joint ventures. They can strongly affect the quantity of technology transferred, the distribution of gains to the agents involved, and any additional innovation in the importing country stimulated by the acquisition of the new technology (Cheng, Pugel). In addition, policies that either affect transfer directly (patent rights, licensing regulations) or indirectly (trade policies, industrial policy) can have a significant impact on the willingness of private companies to trade in technology.

The authors are economists with the Resources and Technology Division, Economic Research Service, U.S. Department of Agriculture. Senior authorship is shared.

The views developed in this paper are the authors' and do not necessarily represent the views or policies of the Economic Research Service.

¹ The private sector is a major source of new technology in agriculture. For example, it spent about \$2.3 billion in 1984 on research and development activities, accounting for about 60% of all such expenditures in agriculture (Pray and Neumeyer). Of this total, it is estimated that \$638 million was spent on chemicals, \$290 million on farm machinery and equipment, and \$954 million on human food (Pray and Neumeyer).

In typical transfers of technology, for example between input sectors, the technology supplier may be able to structure the contract for the transaction to increase the benefits received. The concept of a technology contract is more appropriate than price because technology transfer is often associated with financial payments, which may include lump sums and payments based on revenues or profits from the use of the technology, and nonfinancial conditions that specify how and where the technology may be used and in which markets goods produced using the technology can be sold. The technology supplier may also be able to include certain clauses into the contract to mitigate appropriability problems resulting from public good characteristics of the technology.

By altering the contract to fit the needs of the supplier and user, such channels may encourage technology transfer that would not occur otherwise in a market economy. For example, if market-like transfers are stifled because of market and/or government failure problems, these alternative transfer channels may also be welfare improving in a Pareto sense. How the gains from technology transfer are distributed across different groups will depend, therefore, on the attributes of the technology, industrial organization in the relevant markets, and the terms of the contract.

The structure of the contract for the transfer of technology is of primary interest here. To organize our discussion, the paper contains two main sections. First, following Rees, we develop an economic model of technology transfer using a principal-agent framework. This framework is applicable to a broad range of problems that seek to characterize the optimal form of a contract between two parties who face a range of actions and an uncertain state of nature. Looking at technology transfers as a principal-agent problem is useful because it allows us to analyze some important features of international trade in agricultural technology such as private sector transfers (and the payments associated with them) and uncertainty regarding agricultural and trade policies.

After the basic model and assumptions are outlined, several modifications to the basic assumptions are suggested to investigate how agricultural and property rights policies affect the incentives for technology transfer and the gains from such trade. Given the increasing role of the private sector in technology development and tensions in international policy arenas over trade barriers and internal supports, the economics of private-sector technology transfer is a crucial, yet poorly understood, component in assessing the effects of agricultural technology transfers.

Private Sector Technology Transfer

Consider a simple world with two countries, A and B, each with an agricultural output sector, an agricultural input sector, and a government sector. The agricultural output sector uses foreign and domestic inputs to produce goods for domestic and foreign consumption. Country A's agricultural inputs are also manufactured using technology developed in country B. Imported technology is acquired through two private channels: from one input sector to another, and from country B's input sector to country A's government sector.² Both governments also institute policies that directly and indirectly affect the development and transfer of agricultural technology. In terms of a principal-agent framework, the technology importing firm in country A is the agent, while the technology supplier in country B is the principal. The agent uses the technology and other inputs, a , to produce revenue, x . The particular value of revenue, x , depends on the agent's choice of a and the random variable, z , which the agent and the principal observe after a is chosen. The random component of the revenue function can be attributed to a number of sources. For our discussion, the random component represents shocks to the derived demand for agricultural inputs caused by uncertain agricultural and trade policies such as tariffs, quotas, and internal supports.³ Conse-

quently, the agent's revenue function depends on the degree and type of commercial policy used in the agricultural output sector.

In general, the revenue function of the agent who uses the principal's technology is $x(a, z; c)$ where c represents possible nonfinancial conditions or clauses specified in the contract for the use of the technology. For now, it is assumed that the agent and the principal know the revenue function and can observe the value of x . Let y denote the portion of the agent's revenues from the use of the technology that are used to pay the principal. The technology contract, defined as $Q(y, c)$, stipulates the terms under which the agent can use the principal's technology.

A basic issue revolves around whether the principal can observe *ex post* either the agent's actions a or the observed value of the random variable z . For the moment, we assume that the principal can observe either a or z , and through x can deduce the other. Thus, the basic model is one of Pareto-efficient risk sharing between the principal and the agent (Rees). Under these assumptions, the payment y depends explicitly on z , and the basic model involves the principal choosing $a, y(z)$, and c from relevant choice sets to

$$(1) \quad \max \int_0^1 u(y(z))f(z)dz \text{ s.t. } \int_0^1 v(x(a, z; c, z') - y(z), a)f(z)dz \geq v^*(z', z) \\ \text{where } v^*(z', z) = \int_0^1 v(z', z)f(z)dz,$$

where $u(y)$ and $v(x-y, a)$ are the principal's and the agent's Neumann-Morgenstern utility functions; $v^*(z', z)$ represents the agent's expected reservation utility; z' represents policies that affect the structure of intellectual property rights in the agent's country, such as patent protection and licensing restrictions; and $f(z)$ is the probability density function over the assumed range $[0, 1]$. The structure of international property rights, indicated by z' , enters the problem through the effect on the agent's revenues and reservation utility, v . This point will be discussed in the following section.

Following Rees, the variable a is assumed to yield disutility to the agent and is interpreted as the effort or expenditure by the agent in creating revenues. The choices of a and c are determined prior to observing the state of the random variable, but the payment for the contract may depend on the observed value of the random variable. Thus, in the risk-sharing case, the Pareto-efficient contract $Q(y^*(z), c^*)$ is the solution to the above problem (1).

² Public sector transfers are generated by the government sectors and include aid (capital and good transfers), exchange of scientific personnel, and international research activities.

³ This specification acknowledges an intertemporal component: input suppliers consider future demand for their products, which is directly affected by policies that influence agricultural production. The random component could also represent uncertainty associated with adopting new technology. For example, the technology may perform less well under certain environmental conditions, or certain preconditions that are not clearly known prior to using the technology must be met to use the technology successfully.

The model involves a true moral hazard problem when the principal cannot observe a and z . In this case, the technology contract must be based on observed variables to the principal, which is often assumed to be revenues x , so the contract in general becomes $Q(y(x), c)$. When moral hazard is present, an additional incentive constraint needs to be added to the model outlined in (1) because the principal can no longer design a contract to force the agent to choose the optimum defined for the Pareto-efficient risk-sharing solution.

Implications for Alternative Transfer Channels

While the above model may seem somewhat general, its basic implications can yield some insights into previous studies of agricultural technology transfer. For example, in an international context, it is not at all clear that the principal can observe the agent's actions a or the random variable z . One implication of such a situation is that the firm may have an incentive to change its basic structure to mitigate such problems. For example, rather than attempting to structure a complicated technology contract to deal with moral hazard problems, the principal could acquire an equity holding in the agent to improve observability of a , z , and/or x . In fact, the option of altering the basic structure of the firm, namely foreign direct investment, is one common form of international technology transfer and may be one method to mitigate moral hazard problems.

A transactions cost and monitoring story, which falls under the rubric of "internalization theory," is offered to explain foreign direct investment.⁴ In this view, direct investment involves a transfer of money capital and also a transfer of other resources including management services, technology, and "firm-specific knowledge" which, because of public good and monitoring problems, may be associated with appropriability problems. Thus, in this view, foreign direct investment may allow certain transactions to take place within multinational enterprises (MNE) that otherwise would not have occurred.

That foreign direct investment (FDI) is an important factor in international trade is clear. As

of 1984, the world stock of FDI was about \$599 billion, with the U.S. accounting for about 40% of the total. By 1987, U.S. FDI grew to \$309 billion (U.S. Department of Commerce). The United States is also the home for a substantial portion of FDI, about \$262 billion as of 1987. The quantity of trade destined for foreign-based subsidiaries, which is one indicator of the importance of foreign direct investment as a technology channel, is substantial in the U.S. economy and in the agricultural sector specifically. For example, in 1986, about 40% of all U.S. trade occurred between U.S.-based parent companies and their foreign affiliates, or U.S.-based affiliates of foreign based parent companies (U.S. Department of Commerce). In U.S. merchandise trade, exports from U.S. parent companies to their foreign based affiliates accounted for about \$57.5 billion, or about 27.5% of total U.S. merchandise exports (excluding mineral fuels) (U.S. Department of Commerce). As of 1986, U.S. direct foreign investment abroad totaled \$10.6 billion in food industries, \$23.0 billion in chemicals, and \$22.4 billion in machinery.⁵ In 1986, the foreign direct investment position in the U.S. was \$11.8 billion in food industries, \$22.9 billion in chemicals, \$3.8 billion in non-electrical machinery, and \$1.2 billion total in agriculture, forestry, and fishing.⁶

Once intrafirm trade is considered, the question of intrafirm prices, known as transfer and/or internal prices and the more general concept of a technology contract becomes important. For example, beyond direct pricing mechanisms, the U.S. Department of Commerce reports that intrafirm loans are a major source of funding for affiliated trade. The literature on multinational enterprises seems to view foreign direct investment as establishing similar objectives for the parent company (the principal) and the subsidiary (the agent), and that transfer prices can be used to the overall advantage of the MNE, perhaps at the expense of other countries, especially developing countries. As a result, many governments have established rules and regulations to limit the scope for transfer pricing.

Another important channel of technology transfer is technology licensing, which is a form

⁵ Of total U.S. MNE exports in agricultural-related industries in 1970, intrafirm trade accounted for 34% of the total in the food industry, 36% in chemicals, and 49% in farm machinery (Grimwade).

⁶ In the U.S. for 1977, related-party imports as a percentage of total imports were: 20% in beverages and tobacco, 23% in fish, 40% in fruits and vegetables, 19% in oilseeds, 38% in crude fertilizers and minerals, 43% in chemical elements, 23% in manufactured fertilizers, and 60% in machinery (Grimwade).

⁴ Foreign-direct investment occurs when a parent company establishes a subsidiary in another country or when a parent firm acquires a controlling interest in an overseas company, where a controlling interest implies at least 10% ownership of equity capital of the firm (U.S. Department of Commerce).

of nonequity international transfer of management services and technology that can occur between independent firms (and governments), a parent company and a subsidiary, or two firms involved in a joint venture. Licensing arrangements are contracts between an owner of technical knowledge and a potential user. The license contract often involves a lump-sum payment and a royalty fee based on a percentage of revenues or profits from the use of the technology. In 1981, for example, the United States was the destination of \$7.2 billion, or about 50% of total world licensing income, of which \$5.8 billion came from foreign affiliates (\$1.3 billion in developing countries) and \$1.4 billion was through unaffiliated trade (Grimwade).

Besides the payment stipulated in the licensing contract, clauses are often written into the contract that allow the principal to retain further control of the technology. Such clauses include restrictions on sharing information, using the technology for reasons other than that stipulated in the contract, and geographic location of production. In addition, certain standards of quality in the produced good may be stipulated, and firms may be required to purchase specific inputs in conjunction with the licensed technology.⁷

Katrak analyzes the case where a firm acquires a foreign technology through a licensing agreement that includes a fixed lump-sum payment and a payment based on a percentage of the firm's revenues. In the Katrak model, where both the technology supplier and the importing firm are profit maximizers and there is no uncertainty, it is shown that the importing firm prefers a lower payment based on revenues with a higher lump-sum payment for any total contract value. The logic is that a payment based on revenues reduces the incentives to innovate further after the transfer of the technology.

In terms of the model outlined in (1), when both the principal and the agent have constant absolute risk aversion r_a and r_p , respectively, a linear contract of the form $y(z) = bx(z, a, c) + d$ is an efficient way to share risk, where $b = r_a / (r_a + r_p)$, and d is a lump-sum payment. However, only when the agent is risk neutral is it efficient from the agent's perspective to push for a lump-sum technology contract because a lump-sum contract places all the risk of using the technology on the agent. Thus, there is a trade-off between risk sharing and the incentives for domestic innovation. Further analysis of this

trade-off is possible using the framework outlined in model (1).

Effects of Agricultural Policy on Technology Transfer

The pressure to restructure international agricultural policy is clearly evident. Since 1985, U.S. agricultural programs have reduced support levels and removed some of the incentives to increase yields. In the international arena, the current GATT negotiations are striving to reduce both internal and external support in developed countries in favor of a more market-oriented system. In addition, the developing countries are arguing in favor of reducing trade barriers on tropical products. While the induced-innovation hypothesis suggests that the development of new technology depends on domestic and international economic conditions, little attention has been directed to how agricultural policy influences the terms and, therefore, the welfare impacts of technology transfer.

Within the context of the model developed here, agricultural policies affect the agent's revenues and reservation utility level through the variable z .⁸ For a small country, which can take international prices as fixed, subsidies for producing commodities in the agent's country increase agricultural output and increase the derived demand for agricultural inputs, whether produced with the imported technology or not.⁹ Thus, the agent's revenues and reservation utility level may increase with a production subsidy. Whether the principal is also better off with the subsidy depends on whether the total value of the contract arises or falls with the policy change. For the case of constant absolute risk aversion discussed earlier, the variable portion of the payment will increase, but the fixed portion of the contract will rise or fall as necessary to maintain the agent at the new higher reservation utility level. Thus, in general, a production subsidy could improve or reduce the principal's utility.¹⁰ Conversely, removal or reduction of the production subsidy in a small economy case could result in a decline in commodity out-

⁸ Similarly, the agent's revenues and reservation utility can be determined partially by trade policies, such as tariffs or quotas on agricultural commodities. Any anticipated change in the level of a tariff can affect demand in the agricultural output sector for imported technology.

⁹ If there are quality differences between inputs produced with domestic and foreign technologies, then policy will affect the derived demand for the inputs differently.

¹⁰ Consumers are worse off in the agent's country if they finance the government, which incurs larger costs to finance the subsidy.

⁷ For example, for many years Argentine tractor producers who were subsidiaries of international firms were required to use local inputs in most phases of production.

put and reduce agricultural revenues. The agent's utility falls, but again the principal's utility may increase or decrease.

Currently, many developing countries face significant trade barriers on processed products through tariff escalation policies. Restrictions on exports of processed products has probably limited local technological innovation and dampened the demand for foreign processing technology. In terms of the model developed here, the agent's revenues from food-processing activities are reduced when trade policies restrict the demand for the agent's output. Removing or reducing trade barriers probably would increase the demand for foreign processing technology and/or increase the level of local research and development activities. However, as Mowery and Rosenberg point out, it may be difficult for a country to catch up after years of preferential treatment that allowed foreign producers to gain and maintain market share in processed products.

Restructuring trade policies may also influence the level of direct foreign investment in the agent's country, given that the proliferation of MNE's is partially attributable to tariffs and nontariff barriers that would prevent the principal from directly exporting to the agent. Reforming agricultural policies could increase export sales and remove some of the incentives for firms to invest in overseas subsidiaries, thereby having a dampening effect on technology transfer. For example, MNE activity is particularly strong in the pesticide and food-processing sectors, and a major contributing factor to increased overseas investment has been attributed to tariff (and nontariff) barriers to trade (UNIDO, Handy). The Argentine tractor industry provides an excellent example of the effect of tariff and agricultural policy on input industries. Until the late 1970s, Argentina's tractor industry was composed of subsidiaries of multinational tractor manufacturers. In 1978, a significant decline in MNE tractor production occurred due to policies that fixed agricultural prices below world market price and reduced tariff rates on imported tractors (Sievers).

Changing Intellectual Property Rights

There is a stylized view that improving the excludability of technology benefits, such as through changes in the international structure of intellectual property, will increase private-sector incentives to invest in technology develop-

ment, increase the transfer of technology across countries, and increase earlier disclosure of the innovation. The combination of these events is also thought to stimulate research by the firm (or country) that purchases the patented product.¹¹

In the model presented above, the agent's revenues and reservation level of utility depend on the degree of intellectual property rights protection in the agent's country, represented in (1) as z' . Within the current GATT negotiations, which contain provisions on international property rights, major technology-supplying countries are arguing for tighter restrictions on the use of foreign technology. The impact of a change in the structure of intellectual property rights can be examined using two simple scenarios. Let $z' = 0$ represent the case of no protection for foreign technology, and $z' = 1$ be the case of full protection. In the case of no protection, the agent uses the foreign technology without paying for the right to do so. In this case, the agent's utility obtained through pirating the technology, denoted here as $v^*(z' = 0, z)$, is greater than that which could be obtained from using some other existing technology, v .

If the structure of international intellectual property moves to full protection, $z' = 1$, the principal and the agent would have to agree on a mutually acceptable contract for the technology to be transferred. Because of the policy change, the agent's reservation utility level becomes $v < v^*(z' = 1, z) < v^*(z' = 0, z)$, and the principal can obtain some benefits from transferring the technology. Thus, the agent is worse off having to pay for the technology. The agricultural sector may be better or worse off, depending on the level of inputs produced with the legally imported technology; the quality of the input; and whether patent production encourages increased technology transfer from other suppliers. These issues are yet to be resolved.

Conclusion

Couching technology transfer within a principal agent framework allows us to focus on a number

¹¹ However, as Adikibi observes for the Nigerian case, the terms by which patents are actually utilized in the particular country determine whether in fact any knowledge is transferred/utilized in a country. In the Nigerian case, because of basic problems in design and implementation in the Nigerian patent systems as well as multinational corporation contracts for the economic exploitation of patented information, patents owned by foreign companies were not actually utilized in Nigeria. Thus, patents did not imply technology flow, disclosure of inventions, or further innovation based on the patented technology.

of salient features that describe international trade in agricultural technology. These features include the increasing importance of the private sector's role in transferring technology and uncertainty regarding agricultural and trade policies. An examination of the channels of transfer indicate different impacts on the transferring and receiving countries depending on the degree of uncertainty, the channel of transfer, and the type of public policies implemented. Assessing the costs and benefits associated with technology transfer will likely become more important in agriculture as countries face a more competitive environment in both technology and agricultural trade.

Further research needs to address these issues in more detail to help determine how contracting behavior changes over time or why some firms favor certain kinds of contracts depending on the type of technology transferred, the degree of uncertainty and the level of government intervention. In addition, we need to explore the implications of policies, other than reforms in property rights, that directly affect the creation and international flow of technology.

Technology Policy and Agriculture: Discussion

John Reilly and Roger Conway

The papers address two important forces affecting agricultural research and development: (a) how technology trade and innovation fit into an increasingly integrated world and agricultural economy and (b) the changing roles of public and private funding.

Evenson adds an empirical foundation to the issue of technology flows among countries, a major contribution despite the difficulties of using patent data as an indicator of inventiveness. Three broad points of interpretation are worth emphasizing. First, considerable caution should be used in interpreting a decline in U.S. patenting in the 1980s as a decline in inventiveness. Poor protection of intellectual property rights abroad and increasing internationalization may have provided a growing incentive for firms to use trade secrets even though property rights were protected in the major developed countries considered by Evenson. Comanor and Scherer, for example, found a secular decline in the propensity to patent. Additionally, changing quality of patents, relative propensity of large versus small firms or of firms in different countries to patent, differences in patent laws across time and countries, and relative likelihood of process versus product patenting all affect the accuracy of using patents to compare inventiveness across countries, industries, and over time. Bosworth suggested weighting a patent by the number of years it remains extant as a measure of quality. Scherer notes that larger firms tend to issue patents on minor advances at a great rate.

Second, if private sector inventiveness has actually decreased in the United States, it is likely indicative of reduced research and development (R&D) opportunity or effectiveness because, as

Frisvold reports, real private R&D expenditures in the United States have increased at an average rate of 2% per year during the 1970s and 1980s. This means the cost of maintaining agricultural productivity gains and the historical trend of declining agricultural commodity prices increased in the 1980s. The decline in inventiveness, however, is a big if, and the future implications are unclear. The 1980s may be one of the cyclical patenting downturns evident in Evenson's data. Such downturns may represent slow start-up periods during which research activity shifted to new opportunities. Biotechnology may have been such an opportunity in the 1980s with, perhaps, the patenting payoff yet to come.

Third, while the relative loss of U.S. inventiveness is consistent with the general observation that research has picked up abroad as many countries have caught up technologically with the United States, the welfare implications for the United States are unclear. In terms of overall national competitiveness, the important question is who appropriates the returns to invention. With internationally diversified stock ownership, multinational companies, and research and field-testing to take advantage of countries with favorable climates (in both the sense of weather and regulation/economics), the country where the invention is first patented may not be the country that appropriates the gain from a patent. Even accepting a relative loss of U.S. inventiveness, a broadening of inventive activity beyond the United States would be beneficial through lower world commodity or input prices. Another explanation of the trend is that gradual reduction in U.S. agricultural technology isolation may have led to an increase in technology imports indicating a shift in demand for imported inventions rather than a failure of U.S. inventiveness supply. U.S. companies may have, appropriately, shifted R&D funds from devel-

opening new patented products to marketing already developed technologies. This interpretation would again lead one to welcome the trend toward increased technology imports because it would increase the competitiveness of the U.S. technology users.

Anderson and Larson analyze private firm, international technology transfer using a principal-agent approach. Focusing on the relationship between inventor and user raises directly the issue of how the gains to invention are shared in contrast to Evenson's data on who invents. The model highlights the need for firms to be flexible in exploring alternative strategies for transferring technology including, for example, arms-length licensing, creation of subsidiaries, and cooperative and joint development projects. It would be useful for the authors to develop a greater degree of structure to their model. While such structure would limit its applicability, greater insight would be provided into the specific conditions where it remained applicable. We raise several specific points below.

While there is a principal, i.e., the inventor, technology diffusion and licensing may include multiple agents. For example, an inventor may consider many agents until the agent (company or country) willing to negotiate the most favorable deal is found. In Anderson and Larson's model, the successful agent will be the one with the lowest level of risk aversion because this agent would be willing to accept the most risk. Large companies that can successfully pool risk across numerous new inventions may be willing to accept considerably riskier individual projects. If (companies in) developing countries are more risk averse, such a conclusion would explain a bias against rapid diffusion in developing countries. A single agent model also does not address why an inventor may license the invention to multiple agents rather than grant an exclusive license trusting the single agent to appropriate benefits across countries.

Anderson and Larson interpret the problem as one where the principal (the inventor) is relatively information-deficient relative to the agent. Presumably, the principal would have more complete access to the technology performance and therefore may have an information advantage. The agent, as well as the principal, could be the victim of moral hazard. The principal has the potential to greatly reduce the value of the licence by establishing additional licenses or by developing succeeding technologies.

The authors contrast their model with trans-

actions cost models, but the principal-agent formulation appears to be a special case of the transactions cost approach. Williamson identifies small numbers, information asymmetries, and bounded rationality as key elements that give rise to transactions costs and lead to internalization. The principal-agent problem is the special case where the small number is two, i.e., one supplier and one demander.

The authors also suggest analysis of the small country case where agricultural prices are fixed. One must exercise caution because, if the technology inventor fully exploits the technology, it means that the commodity price will fall in most cases.

The authors conclude that any restrictions on private sector transfers could result in less technology developed, as firms are constrained in earning the maximum return on their investment. The reduction in return may not be as great as one would initially imagine given that commodity trade could substitute for technology trade. If one envisions technology as a factor of production, then results of the Hecsher-Ohlin trade model yielding factor price equalization even with restricted trade in the technology factors apply, i.e., the technology would receive the same return whether traded or not if there were trade in commodities.

Frisvold, and Knudson and Pray deal with public versus private roles for R&D. Each provides a unique interpretation of the public R&D funding decision. A shortcoming of both papers is the treatment of the private R&D decision as exogenous. The more general model would view levels of each as jointly determined. In this regard, the Frisvold conclusion that the public sector should alter its research agenda to complement that of the private sector follows directly from the assumption that private sector R&D is predetermined. The apparent complementarity of some private and public R&D in Knudson and Pray's paper is a challenge to Frisvold's assumption of substitutability. Knudson and Pray's formulation of the SAESs as budget maximizers is an important and useful departure from the traditional assumption of fixed budgets. The results are intriguing but a fuller discussion of the data would be helpful. A more complete theoretical derivation of the empirical model would also help clarify the choices implicit in the model variants estimated. Because few of the coefficients remain significant and several change sign over the various specifications, it is difficult to draw general conclusions.

Technology Policy and Agriculture: Discussion

Marie E. Walsh

Agriculture is already technologically sophisticated and will become increasingly so as new biotechnologies and information technologies become available. Increasingly, however, agricultural technologies and practices are being questioned for their environmental, food safety, and animal welfare impacts. Society is concerned about the distributional impacts of new technologies as well as efficiency implications. Policy makers are faced with designing agricultural policies that consider these impacts. Agricultural economists can assist this process by evaluating the costs, benefits, and tradeoffs that society must face with respect to new technology development. They can play a potentially significant role in the design of technology policy to encourage the development of new technologies deemed most suitable by society.

The organizers of this session asked me to evaluate these papers from a policy perspective and to discuss their contribution to the policy-making process. As such, my comments are likely to be more critical of the papers and the agricultural economics profession than those of the other reviewers. In the area of agricultural technology policy, there is a genuine need to develop sound economic theory, to improve analytical methodologies, and to provide consistent data. In this context, all of the papers extend the knowledge base needed to analyze technology issues. All of the papers present tantalizing possibilities as to how they can be used in agricultural technology policy analysis. The Anderson and Larson paper provides a new way of thinking about international technology transfer and the roles played by intellectual property rights and agricultural policy. The Evenson paper verifies the growing realization that other countries have dramatically improved their technology development capabilities and provides a

much needed data set for further analysis. The Frisvold paper provides a framework for analyzing the allocation of public research funds to achieve market and nonmarket goals. The Knudson and Pray paper provides empirical analysis of the increasingly important issue of the privatization of public research. All of the papers provide improved theory, data, and analytical methodology needed to analyze technology issues, a necessary first step.

My criticisms of these papers and of agricultural technology papers in general arise from the frustrations of someone working in the agricultural technology policy field. Ideally, one would like to be able to find all of the information needed in the agricultural economics literature. However, rarely is the necessary analysis available. All too frequently, agricultural economics journals contain no articles relating to technology issues; and, when articles are present, they frequently are abstract, theoretical, and generic frameworks for evaluating an issue, much as the papers in this session are. Abstract frameworks do not present the type of information needed in a format that is useful to policy makers. Policy makers and their staffs have neither the time, resources, nor in many cases, the expertise to extend a theoretical paper to its logical conclusions and implications. In the arena of technology policy making, theoretical frameworks are often filed and ignored, and as such have a minimal impact on policy.

When empirical studies are conducted, they frequently fail to address the questions of policy interest. Efficiency and aggregate impacts are important, but they are not the only things that are important—issues of equity, distribution, intellectual property rights, environmental quality, food safety, animal welfare, and budget constraints are also on the minds of policy makers. They want to know how policies and technologies will differentially affect segments of the economy and how farms of different size and type and in different geographical regions will be affected.

The challenge for agricultural economists is

The opinions expressed are those of the author and not necessarily those of the Office of Technology Assessment.

to provide policy makers with timely, relevant information on the costs and benefits of different technology policy options and to help them understand the tradeoffs that will occur. *Ex ante* analysis is generally preferable to *ex post* analysis. Rigorous quantitative analysis is desirable, but it is not the only way to participate in the agricultural technology policy debate. A well-constructed qualitative presentation of the pros and cons of specific policy alternatives and the relative direction and magnitude of expected impacts can be invaluable in the design of technology policy. Fortunately, *CHOICES* magazine provides a forum for agricultural economists to discuss important issues and to do so in English rather than mathematical equations, so non-economists can understand. Frankly, in the area of agricultural technology policy, articles in *CHOICES* are frequently more useful than those in the *AJAE* and other agricultural economic journals.

Evenson concluded his paper with the hope that the information provided will inspire scholars to perform further research to test hypotheses and develop policy implications. I wholeheartedly agree. My remarks have been critical on purpose. All of the authors have made an important first step. Sound theory is essential. But for policy analysis, it simply is not enough. I urge agricultural economists to do *ex ante* analysis on specific policy options and technologies and to broaden the issues that they address to include nonmarket values and distributional implications. Failure to do so will preclude agricultural economists from participating in the agricultural technology policy debate and from making contributions that they are so capable of making. Considering the increasing importance technology issues will have on agriculture, failure to participate actively in this debate is an embarrassment to the profession and one that I hope will not occur.

Technology Policy and Agriculture: Discussion

James F. Oehmke

The papers by Anderson and Larson, and Frisvold are similar in that each paper advocates the application of theories developed for other problems to technology generation and transfer: Anderson and Larson suggest greater application of the principal-agent paradigm, while Frisvold suggests greater use of industrial organization (among other) results. Although the advocacy of new applications is extremely ambitious, these papers make some progress toward their goals. The papers are similar in their style of argument. Each paper provides a brief description of the relevant theoretical results, discusses why some of the theoretical assumptions may (or may not) be appropriate for modeling technology generation or transfer, and gives a taste of policy implications that can be derived from these theories.

However, in part because of the ambitious goals, these papers are not completely successful. For example, Anderson and Larson's discussion of policy effects on the Argentine tractor industry is unconvincing: Why is a principal-agent framework needed to indicate that if prices are below the equilibrium level, then output will be below the equilibrium quantity? Similarly, Frisvold's discussion of quality-improving research does not seem to depend on the industrial organization of the market; demand shifts which raise equilibrium price tend to decrease the costs of a target price program when target prices are set above the equilibrium price under most imaginable industry structures.

Each of these papers would be greatly improved by focusing on one or two observations or empirical regularities which are not explained adequately by existing models of technology generation and transfer. This will entail greater discussion of the behavior to be explained and of the failure of existing models to explain this behavior. For example, Anderson and Larson would be more convincing if they compared the implications of the relevant principal-agent model

to other explanations of multinationals, such as noncompetitive markets (e.g., Krugman) or factor endowments (e.g., Dinopoulos, Oehmke, and Segerstrom), and found that the principal-agent framework best matched empirical observation. Perhaps the existing models do poorly in situations where risk is an important consideration.

Despite my reservations, I encourage the authors to pursue these lines of inquiry by developing more detailed models which yield testable implications. I agree with Frisvold's recommendation that revealed preference arguments may provide a better understanding of government behavior toward public research (e.g., Oehmke and Yao). I particularly agree with his recommendation for the establishment of a better data base on private R&D. It is impossible to determine which models have the most accurate behavioral implications without accurate data.

Evenson contributes to our understanding of private R&D by examining patent data. This paper does an excellent job of finding information on private R&D outputs, which is normally difficult to obtain, and of organizing the data in an informative manner. Three intriguing facts emerge: (a) the annual average number of U.S. agriculturally related inventions patented in the United States fell between the 1970s and 1980s, while the annual average number of foreign inventions patented in the United States rose over the same period (Evenson, tables 1-3); (b) the absolute number of U.S. patents has declined in the 1980s from the 1970s (Evenson, tables 1-3); and (c) the United States has been a net exporter of patentable, agricultural inventions to France, Germany, and the United Kingdom over the 1960-87 period (Evenson, table 4).

The data presented in this paper raise a number of important questions: Does the recent decline in the number of patents portend a time of stagnating agricultural productivity? Is the increased percentage of U.S. patents originating in foreign countries a result of technological factors such as a relative decline in U.S. research productivity, monetary factors such as fluctuating exchange rates and the strong U.S.

James F. Oehmke is an assistant professor, Department of Agricultural Economics, Michigan State University.

dollar, or other causes? Is the increased importation of foreign technology a signal of declining U.S. technical competitiveness, or is it socially beneficial because it makes improved technology more easily available to farmers and processors?

Pray and Knudson focus on the interaction between the public and private research sectors in a political economy framework. As Frisvold points out, this is an important direction of research. Pray and Knudson's regression analysis shows the importance of the private sector and incentives designed for the private sector in determining the level of public research expenditures. The three most interesting explanatory variables in this analysis are private research expenditures, which have a negative but not statistically significant effect on public expenditures; potential public-sector royalties from public-sector research, which has a positive and in one case statistically significant effect; and industry contributions to experiment stations, which has a positive and significant effect. Because the data are separated by commodity, the last result can be interpreted to mean that private contributions can redirect the commodity focus of experiment station research.

The regression analysis could be improved in further work. Annual observations should be available for the data. Use of annual data would allow investigation of questions such as incrementalism in the budgeting process. The number of observations would be increased sufficiently to test hypotheses about differential effects of private sector actions on different commod-

ities. While such hypotheses are discussed in the text, they are not testable in the current regression framework.

One peculiarity in the paper is the discussion of private sector "crowding-out" of public sector research. This direction of effect suggests that the public sector has a comparative advantage in research relative to the private sector. While those of us committed to public institutions accept this as fact, the industry as a whole may not be so lenient.

Finally, Pray and Knudson examine the implications of their regression analysis for optimal allocation of research expenditures. Using their (admittedly crude) measure of social benefits, they find that industry contributions to the public sector push the cross-commodity allocation of public research funds closer toward a social optimum. This intriguing phenomenon deserves more thorough empirical investigation and conceptual explanation.

The Effect of the 1990 Farm Bill on Agricultural Trade

George E. Rossmiller and Rachel A. Nugent

A struggle has taken place across the Atlantic between the pocketbooks of the U.S. federal government and the European Economic Community during the 1980s. The battlegrounds have been importing countries that have received heavily subsidized exports of agricultural goods from the two big producers. The casualties are competing exporters and those, often third world countries, who would produce and perhaps even export agricultural products in an undistorted world market. Two major policy events during 1990 threatened to alter the weapons and fortunes in this trans-Atlantic struggle: reauthorization of the five-year U.S. farm legislation and the global trade negotiations under the GATT. This paper reviews briefly the status of these two events and summarizes expected trade impacts.

Both events promised to address long-standing imbalances in agricultural markets. The combination of policies in the United States and EC, increases in farm yields, and saturation of domestic markets had led to recurring conditions of excess capacity, turbulent farm sector economies, and competition for international markets. These trends began with policy changes in the early 1970s that contributed to huge government outlays as the 1980s progressed.

Pressure to alter the policy course became severe in the United States as government support for agriculture soared and high loan rates in the 1981 Farm Act curtailed U.S. markets overseas. The 1985 U.S. farm legislation increased market competitiveness by lowering loan rates and maintained target prices at 1985 levels for two years before phasing in a 10% reduction between 1988 and 1990. The EC was likewise making marginal policy changes that would reduce its budgetary exposure and lower payments to farmers on selected commodities. The result was eventual lowering of budget outlays, but not

before they peaked at an all time high of \$26 billion in the United States and over \$30 billion in the EC in 1986.

Countering the trend toward lower support, both the EC and United States were actively vying for export markets by selling commodities at substantially cut-rate prices. The United States initiated the Export Enhancement Program (EEP) to directly counter the EC's export subsidies in designated markets.

The strong budgetary commitment continued steadily until a pause caused by the North American drought of 1988. World market prices rose as a result, and U.S. and EC government costs of agricultural programs plummeted. Strengthened prices and lower subsidies did not last, however, as the underlying trends causing surpluses resumed.

1990 Farm Bill

The debate over the 1990 U.S. farm bill began as a whisper. On most issues, participants were content to maintain the elements of the 1985 farm bill, at least until the outcome of GATT trade talks was known. It was widely expected that the real changes would come after a GATT agreement and would be incorporated into a 1991 farm bill.

The 1990 farm bill did make some change in farm programs. The legislation written during the summer and fall froze target prices throughout the life of the bill, controlled production through acreage reduction and conservation reserve programs, and increased farmers' flexibility in planting decisions. The bill carried a pricetag of about \$55 billion for the 1991-95 period—about \$2 billion-\$5 billion more than continuing the features of the 1985 farm legislation over this period.

In October, when the drafted farm legislation was being finalized by a conference committee, Hill negotiators and the Bush administration

George E. Rossmiller is director, National Center for Food and Agricultural Policy, Resources for the Future; Rachel A. Nugent is an economist with the National Security and International Affairs Division of the General Accounting Office.

agreed on a deficit reduction package to avoid the more stringent budget cuts that would have been necessary under the Gramm-Rudman-Hollings Budget Reduction Act. Farm support programs were among the most severely affected. Budget negotiators informed the agriculture committees they must cut \$13.6 billion from the five-year legislation—about a 25% decrease—with \$1.4 billion in immediate cuts for fiscal year 1991. This was still less than the 32% cut that would have been required under Gramm-Rudman-Hollings for fiscal year 1991. Direct support reduction in 1991 is estimated at about \$500 million under the Budget Reconciliation Act versus an estimated \$2 billion reduction had a Gramm-Rudman-Hollings sequestration taken effect. The budget summitters effectively forced some policy changes in farm programs that were politically infeasible if left to the agriculture committees on the Hill.

One of the primary cost-cutting measures adopted was the so-called "triple-base" for cereals and cotton. The triple base reduces crop acreage eligible for support payments by a mandatory 15% (and an additional optional 10%) while allowing farmers to grow crops on that acreage (including program crops) and sell those crops at whatever price the market will provide. In effect, a farm is divided into one section that is eligible for full program payments, another section that must be idled to comply with acreage reduction requirements, and a third section that can be planted in any crop (other than fruits or vegetables) to provide earnings not subject to government subsidies. The triple base has the effect of decoupling production at the margin from government payments. This will likely prove to be the most important policy change in the 1990 legislation.

Some of the other notable budget-cutting measures included in the deficit package are a change in the calculation of average market prices from a five-month to a twelve-month basis so that a higher market price basis is used to calculate deficiency payments, new loan origination fees and service charges for program participation, and a move to guaranteed loans from direct loans for Farmers Home Administration and Rural Electrification Administration lending programs.

The budget reconciliation bill contains some major adjustments in the event there is no GATT agreement by July 1992. Specifically, \$1 billion must be provided for export promotion (EEP), a marketing loan program for wheat and feed grains must be instituted, and acreage reduction

minimum requirements may be waived. If an agreement is concluded but not implemented by July 1993, the secretary of agriculture must consider waiving the spending reductions in the bill, increasing funding for export promotion, and instituting a marketing loan for wheat and feed grains. This clause was insisted upon by Capitol Hill in an effort to put additional pressure on the European Community in the GATT negotiations.

Impact on Trade

The effect of the combined 1990 farm bill and the budget reconciliation act on the composition and level of agricultural production and trade is unclear for several reasons. First, the triple base allows farmers to plant alternative crops on up to 25% of their program crop base without losing program base acres. Presumably, farmers will make this planting decision, at least at the margin, based on expected market returns of the commodities they are technically able to produce.

But government support for farm incomes is substantially reduced. With the frozen base yield now significantly below trend yield and the 15% mandatory reduction in program crop acreage eligible for support payments, fully 26% of corn production and 23% of wheat production in 1990 would have been ineligible for support. The percentage of production ineligible for support can be expected to increase with rising yield trends but may vary among commodities depending on shifts in acreage planted to the different crops.

Second, the 1985 act had introduced environmental and conservation compliance requirements that are viewed by many producers as punitive. The 1990 act further restricts eligibility for federal farm programs when producers are not in compliance with their conservation plans. Third, while the \$50,000 deficiency payment limitation per person was retained, the aggregate payment limit was halved from \$500,000 to \$250,000.

In sum, it is likely that program participation will be discouraged by the reduced acreage eligible for support payments afforded by the combination of the triple base and the acreage reduction program, more stringent rules and penalties on environment and conservation compliance, lower payment limits, and lower deficiency payments derived from using a twelve- rather than a five-month average of market prices. Lower program participation is likely over the

life of the 1990 act, particularly in years of expected strong market prices.

In 1991, however, participation rates are likely to remain at or above present levels. This can be attributed to the tumble in commodity prices in recent months, particularly since mid-1990. For example, November 1990 wheat prices were down 31% from November 1989 and 24% from the second-quarter 1990 average. Corn prices in November 1990 were 8% lower than in November 1989, but 16.7% lower than their second quarter 1990 average. Comparable rice price percentages were 12.8% and 4.8%. Cotton prices have been stable during the past year showing a 1.1% increase between November 1989 and November 1990. Soybean prices were down 2.8% from November 1989 to November 1990, with meal prices down 10.6% and oil prices up 5.2%. Thus, with lower prices one might expect participation rates to remain at present levels or even increase until markets recover.

These price relationships also provide clues as to the likely shifts in the production mix, at least for next year, under the triple base. With wheat prices the most depressed of the commodity prices, it is likely the wheat triple base acreage will be shifted to other crops where possible, toward cotton in parts of the southern plains, toward corn in the fringes of the Corn Belt, and perhaps to minor oilseeds in areas where the market channels and processing facilities are available.

The net result of various responses to the triple base is expected to be eventually lower participation rates (after depressed market prices recover), therefore increasing production. The U.S. output and its mix will become more responsive to world market prices. Yet, world market prices may decline with overall increases in U.S. production and exports.

In addition to the triple base, several new program changes may affect trade quantities. Increasing loan rates to 85% of a five-year moving-average market price, eliminating the high and low prices, instead of 75%, ostensibly raises the price floor for wheat and feed grains. However, several complicated adjustments are required or allowed to retain U.S. competitiveness in international markets. A mandatory downward adjustment in the loan rate of zero to 10% depending on the stocks-to-use ratio and a discretionary 10% downward adjustment by the secretary of agriculture to maintain export competitiveness are included in the act. A new marketing loan for oilseeds and limits or potential removal of acreage set-asides may benefit ex-

ports through lower market prices and increase production.

Uruguay Round Effects

The Uruguay Round of international trade talks was expected to bring about a brave new world of global trade relations. Our sights at the moment are considerably lower. In fact, the question of whether an agreement will be reached in agriculture is still open at this writing. The issue has boiled down to the EC interest in reducing direct budget costs of domestic farm programs by reducing support levels but without fundamental reform of the Common Agricultural Policy and erosion of community preference, against the U.S. and Cairns Group interests in increasing market access and placing limits on the ability of all countries, including the EC, to subsidize exports. Because the U.S. and the Cairns Group positions would require fundamental CAP reform that would put community preference in jeopardy, a substantial GATT agreement is not likely in the cards this time around. Thus, it is not likely to have a major impact in liberalizing trade or reducing trade tensions.

Part of the reason the Europeans have offered so little of substance in their negotiating package is the preoccupation in Europe with EC-92 market harmonization, the breakdown of the command economies and the struggle to replace them with market economies in Eastern Europe during the past year, and German reunification. There are substantial potential costs facing Western Europe in handling these events, and even greater costs if they do not succeed in dealing with those issues. In contrast, it appears that a GATT agreement would cost great political and economic stress in Western Europe in the short run, while an agreement presents only vague and intangible long-run benefits.

The EC is likely to become more inward-looking whether or not a GATT agreement is reached. Already heavily focused on the formation of EC-92 institutions, and in need of markets for excess production, the EC is likely to expand membership to include nations from both Western and Eastern Europe. If this significantly expanded trading bloc were to be highly protectionist *vis-à-vis* the outside world, the trend toward formation of trading blocs by other countries would be exacerbated.

This scenario implies a world in which bilateral agreements and independent trading blocs may become the dominant trade structures, thus

further weakening the GATT. Agriculture in the United States and EC would remain heavily subsidized. Developing countries in Africa and parts of Latin America would be kept out of the bidding, with no opportunity to establish growth patterns based on international competitiveness.

Finally, it is accepted wisdom by now that external macroeconomic factors affect U.S. farm income and stability to a far greater extent than previously believed. The world market takes roughly one-fourth of U.S. agricultural output. Changes in demand caused by developing country debt problems, reconstruction in East Europe, oil price shocks, and other macroeconomic impacts greatly alter the potential health

and trade prospects of the U.S. farm sector—more so, in fact, than the 1990 farm bill.

The 1990 Farm Bill and the Uruguay Round

C. Ford Runge

When former Secretary of Agriculture Clayton Yeutter accepted the position, two clear priorities for his term were evident. The first, domestic, priority was to move as far as possible in the direction of a safety-net program for farm income support in the 1990 farm bill. The second, trade-related, priority was to put together an acceptable package in the Uruguay Round of multilateral trade negotiations, in which agriculture would play a central role. This short paper reviews the progress of both of these efforts to date, and assesses the impacts of this progress on the commodity composition, income, and asset values of American agriculture.

This assessment is qualitative. The detailed numerical estimation of these effects is left to those equipped with the large models necessary to estimate them. The assessment is also affected by a variety of external factors which loom especially large at the beginning of 1991. Apart from the unsettled outcome of the Uruguay Round and the economic recession, these include the political and military situation in the Middle East and the breakdown of functioning economies in Eastern Europe and the Soviet Union. Together, these external forces are likely to play a much larger role in determining the fortunes of American agriculture than either the 1990 farm bill or the Uruguay round, at least in the short term.

The 1990 Farm Bill

The farm bill debate of 1990 occurred in essentially two phases. The first was an exercise in political fantasy in the spring and early summer, in which the members of Congress indulged the wishes of a variety of commodity groups with promises of increased levels of support. These

domestic promises were linked to a variety of stern statements that the General Agreement on Tariffs and Trade (GATT) would not lead the farm bill to be "written in Geneva." Fears over this (unlikely) prospect were part of the reason that the 1990 bill ultimately contained "snap-back" provisions which guaranteed that if the Uruguay Round "failed," farmers would be compensated with extra spending on the Export Enhancement Program (EEP), and marketing loans would be instituted for coarse grains and wheat.

During the fantasy phase, the administration issued its own version of a wish list, a green-colored document detailing its proposals for a whole farm base, or Normal Crop Acreage (NCA) scheme, together with a variety of other more-than-incremental proposals, such as the elimination of crop insurance in its current form. While not quite as "dead on arrival" as the Reagan administration's 1985 proposal, the fact that the proposal contained no budget numbers indicated that the administration was engaged in a strategic bargaining exercise.

The second phase of the farm bill process was driven by budget realities, during which most of the fantasies (though not all) were laid to rest both in Congress and at the U.S. Department of Agriculture (USDA). As the "budget summitteers" flailed away in attempts to conform to the Gramm-Rudman deficit reduction targets, it became evident that even major attempts to staunch the flow of red would not contain the hemorrhaging federal budget, especially as recession deepened. Agriculture spending, however, was a virtually unanimous candidate for cuts, and as the need to eliminate roughly \$13.6 billion over five years emerged from the budget talks, it dictated certain moves in the agriculture committees and at USDA that saved money while saving seats.

Because target prices are visible political numbers and had been the focus of much of the fantastic promises made by incumbents seeking re-election, the least politically damaging way

C. Ford Runge is an associate professor and a member of the Center for International Food and Agricultural Policy, University of Minnesota.

Financial support from the Northwest Area Foundation, St. Paul, Minnesota, is gratefully acknowledged.

to find budget savings was by reducing the number of base acres in the major budget programs (coarse grains and wheat) that were eligible for deficiency payments. This budget pressure dovetailed (though not perfectly) with the idea of "flexibility" which had underpinned the administration's argument for NCA. Because total flexibility under NCA was neither necessary to achieve the budget targets nor desirable to many commodity groups and their supporters in Congress, a "triple-base" emerged as a natural compromise. While much else in addition was done or undone in the 1990 farm bill, the "triple-base" was at its heart and was driven primarily by budget pressures rather than deeply felt attraction for a clear step in the direction of decoupling. Such a step it was, however, giving the administration a relatively strong hand going into the December 1990 GATT meetings in Brussels, when it could claim virtue for having moved in the direction of its proposed safety net.

The impacts of the 1990 bill on domestic producers will be mixed. One notable aspect of the "triple-base" is that it plays much more to the advantage of the corn/soybean grower than the wheat grower, especially in the North and Northwest where flexibility, apart from wheat and barley, means canola, sunflowers, or dry edible beans, and not much else. Because neither fruits nor vegetables are allowed on "flex-acres," in essence the bill provides for more oilseeds in lieu of either corn or wheat. In total, the acreage shifts are not likely to be substantial unless the economic environment becomes favorable enough for large numbers of producers to abandon the programs altogether and grow what they please. In the short term, however, the continuing secular decline in wheat prices, aided and abetted by the interaction of EEP and the European Community's (EC) export restitutions, will make farming hard in areas like the Palouse. One curious consequence of the triple base was to promote opposition on the part of many wheat growers to increased acreage reduction programs (ARPs). Many of the same growers had argued in 1985 for mandatory production controls.

While a paper of this length precludes commodity-by-commodity analysis, a word about the dairy sector is in order.¹ Both the 1990 farm bill

and the budget reconciliation act contain provisions which are significant for the dairy sector. Support prices are not to fall below \$10.10 per hundredweight (for 3.67% milk) for several years. And the producer assessment, while only 5¢ per hundredweight the first year, could rise substantially for producers that expand production. This latter provision provides a mechanism for extracting payments in the event supply exceeds demand and may be exercised if output continues to drift upward.

If the experience of the 1990 bill does not discredit "flexibility," even greater steps can be taken in the future to decouple payments from production, to reduce ARPs, and to loosen requirements forbidding non-program crops from being grown, so that the real advantages of NCA can be realized. One area where the 1990 bill fulfilled growers' fantasies beyond all expectations was the sugar regime, which, despite a negative GATT panel ruling, emerged not only unscathed but arguably enriched from the legislative process. This should tell the analyst something about whether farm bills are written in Geneva. Soybeans, which had been held up for years as a model of "market orientation," threw in the towel and sought the protection of a marketing loan, which is in essence no different from the EC's restitutions, although it is set in such a way as to do the soybean grower little good. Having compromised on principle, the soybean growers failed to bring home much of a prize.

The "snapback" provisions of the bill allow for both more EEP spending and the extension of marketing loans to coarse grains and wheat if GATT "fails." These provisions contain the worst elements of both fantasy and reality. On the one hand, they are unlikely to be funded at levels which would realistically be required to truly punish the EC for its intransigence unless the \$13.6 billion spending target is abandoned. On the other hand, they will surely provoke retaliation, in all likelihood leading to even lower prices, especially in the wheat market. It is the threat of such retaliation that would make failure in the Uruguay Round of real concern.

The Uruguay Round

As of this writing, the likelihood for a meaningful package of reforms in the areas of marketing access, internal supports, and export subsidies in GATT are slim. When the EC, together

¹ An excellent briefing on a commodity-by-commodity basis is "The 1990 Farm Act and the 1990 Budget Reconciliation Act: How Farm Policy Mechanisms Will Work Under the New Legislation." Washington DC: U.S. Department of Agriculture, Nov. 1990.

with Japan and South Korea, rejected the Hellstrom compromise proposal in Brussels on 6 December, they signaled that, even if a final deal is achieved, it will fall short of the proposed compromise. That compromise called for 30% reductions in both export subsidies and internal supports on a base year of 1990 (as distinct from the EC's proposed base of 1986) and 30% increases in market access over five years, with a minimum 5% market access guarantee at the outset.

The prospects in GATT are either for something short of the Hellstrom compromise, or nothing at all. In terms of immediate impact on the U.S. farm sector and its balance sheet, either outcome would take several years to show up, unless a trade war erupted quickly in the face of failure. Something close to the Hellstrom compromise would reinforce the logic the "triple-base" by mandating further reductions in deficiency payments and would create an excuse for ending the ill-advised EEP program. The market access provisions would also assist in lower import quotas in sugar and to a lesser degree in peanuts, dairy, and other border-protected commodities. These effects would occur over a relatively long time (5–10 years), giving the farm sector plenty of opportunity to adjust.

One of the ironies of the debate over the Uruguay Round in farm circles has been the paranoia GATT has produced, which has been fed by neopopulist opponents of liberalization. These opponents are usually admirers of supply control and sometimes of the European Community. If the GATT talks fail completely, the irony will be that the retaliation mandated by the "snapback" provisions of the 1990 bill will actually fan the flames of protectionism, leading to attacks on the EC, Japan, and South Korea, which together constitute huge agricultural export customers. If farmers are looking for something to be paranoid about, it should be a trade war, rather than GATT. Such a trade war will have two primary effects. First, it will further depress world markets, leading to even lower commodities prices, especially in the wheat market. Second, it will cost money, which, unless Congress is prepared to reverse its stand on agricultural spending, could mean even less for deficiency payments. If the trade war spreads beyond agriculture to include other sectors of the economy, it would deepen the current global recession, lowering profits and government revenues, putting even more downward pressure on both the demand for agricultural exports and the

ability of government to subsidize them and the farm sector.

Conclusion

What are the overall prospects, given the 1990 farm bill and the unsettled trade picture, for U.S. agricultural incomes, land values, and commodities prices? Essentially, the 1990 bill has set a course leading to greater market orientation, although a few exceptions remain, such as sugar. Yet, the trade picture may mean that at the border, and in the world market, this market orientation is frustrated by the protectionist elements of the world community, notably the EC.

Whether or not a trade war erupts, I would expect the level of farm incomes to stay at roughly current levels or to fall if recession cuts into global demand. The commodity mix of U.S. agriculture will not be affected greatly by the triple-base unless larger numbers of farmers leave the program, which is unlikely in a recession. The linkage from export demand to farm incomes and in turn to land values (see Runge and Halbach) implies that land values will not rise appreciably either and could fall if a trade war erupts.

However, several factors are still unknown which could radically change this picture, probably for the worse. One is the prospect of continued instability in the Middle East, which could raise the price of petroleum and its derivatives and thus farm input prices far more rapidly than it would boost commodities prices. The second is the collapse of the Eastern European economy, which, while apparently offering a market for U.S. grain, constitutes less a paying market with hard currency to spend than a charity case. Both events likely would deepen global recession. In light of the current popularity of bashing our allies for failing to support our efforts in the Middle East, it would not be surprising to see the bashers join forces with the protectionists (many are already one and the same) to call for retaliation against these same parties in agriculture. It is far easier to blame lost jobs or farm foreclosures on Japan, South Korea, or the EC than it is to acknowledge that recession breeds protection, which deepens recession further. This was the same cycle so clearly exposed by Keynes in *The Economic Consequences of the Peace*.

This discussion began by noting that Clayton Yeutter stepped into his position at the Department of Agriculture with at least two broad goals. His efforts to bring greater market orientation to

agriculture must on balance be judged a success, although they are a patchwork, with success in the "triple-base" offset by persistent distortions in areas such as sugar and dairy. His other and related objective—to begin the process of agricultural trade liberalization in the Uruguay Round—foundered on the resistance of the EC, coupled with global recession, tension in the Middle East, and the collapse of Eastern Europe, none of which were entirely predictable. These forces may alter the course of history in ways inimical to greater trade liberalization, although I hope that the leaders of the free world will not err today as they did in

the 1930s, with respect to either protectionism or appeasement.

Impacts of the 1990 Farm Bill on Consumers

Carol S. Kramer

Any U.S. farm bill, including the 1990 "Food, Agriculture, Trade, and Conservation Act," affects domestic and foreign food consumers in numerous important ways: through potential impacts on food availability, food costs, food safety and quality, marketing rules, nutrition provisions, and overall research agenda. In addition, the act influences consumers of environmental amenities explicitly through environmental provisions and indirectly through commodity and other titles. Finally, the farm bill costs money, which consumers pay as taxpayers. This paper highlights some of the provisions of the 1990 farm, appropriations, and budget reconciliation bills likely to prove most significant for consumers in the short and longer term. It also discusses briefly the status of trade negotiations pertaining to "harmonizing" food safety standards for traded goods. Finally, the point is made that much significant food-related policy is not included in the farm bill but has been passed or can be expected to pass piecemeal in other forms of legislation.

The "Food, Agriculture, Trade, and Conservation" Act of 1990

Washington-based analysis of the 1990 farm bill has vacillated between depicting it as largely business-as-usual and a disappointment to reformists, on the one hand; and, on the other, as a dramatic step toward greater market orientation and planting flexibility, with some important new consumer and environmental reforms. The truth, as usual, resides between.

The former view traces the roots of the new act to the Farm Security Act of 1985, as influenced by federal deficit and budget contingencies. It points to the little-changed peanut, sugar, cotton, tobacco, and dairy programs and the newly instituted soybean loan rates. The reformist view emphasizes the triple-base provisions

of the bill, which remove 15% of base acreage from eligibility for commodity payments but permit production of some alternative crops. New environmental and consumer measures include pesticide record-keeping requirements, expanded environmental compliance measures, and certain changes in marketing rules or research affecting fruits and vegetables, grain quality, and organic products.

Complicating assessment of potential farm bill impacts is the massive uncertainty in the global political economy. Uncertainty stems from events in the Persian Gulf, the USSR, the stalled GATT negotiations, German reunification, Eastern Europe, global recession, the vulnerability of the U.S. banking system, among others. At issue is whether the incremental policy impacts of the farm bill will be swamped by the macroeconomic tides loosed by these major political events.

Given all the uncertainties, what does the new act mean for consumers? One could argue that for the consumer the 1990 farm bill may mark a new watershed in some areas, but one that is so far only dimly visible to the careful observer. Principally important are the "green" measures and tendencies in the farm bill: requirements to develop national organic certification standards, to require farm pesticide recordkeeping, to establish new water quality measures, to undertake research into the effects on pesticide use and consumer demand of "cosmetic" grade and quality standards for fruits and vegetables, and to redirect substantial research expenditures toward food safety, sustainable agriculture, and environmental improvement. In addition, in a time of budget austerity, the food assistance programs are reauthorized without significant change: without cutbacks, and containing some measures to make them more accessible to eligible recipients. Finally, outside the farm bill, important new nutrition labeling and nutrition monitoring legislation passed.

The "Food, Agriculture, Trade, and Conservation Act" of 1990 (FATCA) comprises twenty-five titles in a five-year framework for agricul-

Carol S. Kramer is a fellow, National Center for Food and Agricultural Policy, Resources for the Future.

tural and food policy; the first eleven titles deal with specific commodity programs and general commodity provisions. A subsequent mix of titles includes such areas as forestry; conservation; agricultural trade; credit; research; rural development; food assistance; fruits, vegetables, and marketing; grain quality; and organic certification.

The 1990 farm bill has been widely touted for the future cuts implied for farm spending. Development of the farm bill must mesh with the agricultural appropriations process and with the overall budget process as well. Farm appropriations bills begin in the House and then proceed to the Senate, after which a conference committee resolves the differences in light of budget requirements. As agriculture's share of a five-year \$500 billion deficit reduction package, farm spending is now slated at \$40.4 billion, down 25% from the earlier Office of Management and Budget baseline projections of \$54 billion. Of the \$13.6 billion cut during the budget summit, approximately \$8 billion reflects the 15% reduction in cropland acres eligible for farm subsidy payments. Other major cuts are in direct loans made by the Farmers Home Administration and the Rural Electrification Administration. Costs of domestic food assistance entitlement programs reauthorized under FATCA are not expected to change substantially as a result of the bill. Costs of these entitlement programs depend on a combination of factors including program enrollment rates, benefit levels, and food costs, which factor in inflation. No major changes are made in eligibility requirements, benefit levels, or exemptions under the food stamp program. It is safe to say that food assistance expenditures will continue a trend toward relatively greater importance in U.S. Department of Agriculture spending as farm benefits fall and as the economy continues in recession.

Food Assistance Programs

Title XVII, now cited as the "Mickey Leland Memorial Domestic Hunger Relief Act," reauthorizes the food stamp program and related provisions. The food stamp program is reauthorized for five years (through FY 1995), retaining the current structure. The program retains measures that guarantee that households that meet eligibility criteria based on size, income, and assets automatically qualify for benefits. Benefits are still based on the "Thrifty Food Cost" plan as established by the U.S. Department of

Agriculture. The conference agreement authorizes amounts necessary to fund the program. Various House provisions that would have expanded potential eligibility and/or benefits were deleted in conference. However, provisions easing the way for the homeless, students, poor families receiving back-to-school allowances, rural residents who need mail delivery of stamps, and projects designed to increase participation by non-English-speaking minorities, the elderly, homeless persons, low-income working families with children, and rural residents are authorized (Democratic Study Group, U.S. House of Representatives, 22 Oct. 1990). Some food stamp program rules are simplified; additional penalties for fraud and misuse of food coupons are established (U.S. Congress, House of Representatives, news release). Additionally, state agencies are authorized to implement on-line electronic benefit transfer (EBT) systems in which household benefits are issued from, and stored in, a central data bank and electronically accessed by household members at the point of sale.

Other domestic commodity donation programs, including the Emergency Food Assistance Program (renamed from the previous TE-FAP, the Temporary Emergency Food Assistance Program) and the Commodity Supplemental Food Program (CSFP), are also reauthorized.

Commodity Programs/Food Costs

The new legislation freezes target prices and effectively decouples grain and cotton farmers' planting decisions at the margin, moving this part of agriculture a little farther toward market orientation. If a freer market results in more efficient use of resources, consumers should benefit modestly. On the other hand, sugar, dairy, tobacco, and peanut programs remain substantially nonmarket-oriented, with the consumer continuing to bear costs associated with market protection.

Specifically, target prices (1990) are maintained for wheat, feed grains, upland cotton, and rice throughout 1991-95 crop years. Because of flexibility provisions in the legislation, farmers are expected to alter crop choices on their flexible base of 15% of acres toward crops with higher net returns. In 1991, midwestern and northern plains farmers may shift some spring wheat acres into soybeans or minor oilseeds. Some midwestern corn acres may also be planted in oilseeds. If expanded soybean and other oil-

seed supplies result in lower market prices for protein, the effect on food costs would likely be felt through livestock prices. These could eventually reflect lowered costs of protein. Additionally, some of the edible oils could be lower priced. At this time, however, few estimates are available to predict how adjustments might be made to the new policies, and expectations are that effects on food costs will be minor. Ultimately, farm price outcomes for specific commodities will depend partially on how the secretary of agriculture sets acreage reduction program limits, whether to relax ARP acreage to foster competitive export prices or to maintain previous ARP acreage (U.S. Congress, Congressional Budget Office).

In the aggregate, retail food prices include a farm commodity cost component of approximately 30%, although this varies among commodities. Factors outside the aegis of the farm bill such as costs of labor and transportation (influenced by oil costs) often outweigh changes in the commodity cost of food in influencing food prices.

Food Safety and Quality

Consumer and environmental interest groups played an active role in the development of the recent farm bill. Early in the deliberations, a coalition of consumer and environmental groups released their *Farm Bill 1990: Agenda for the Environment and Consumers*. The agenda highlighted agriculture's effects on environmental quality including pollution of surface and groundwater, loss of wetlands, and deterioration and loss of natural resources. The report marked "excessive use of pesticides and nutrients" and pesticide residues in food as major concerns. Many of the concerns and potential solutions mentioned in this influential report in fact became discussion points and, in some cases, resulted in new measures or guidelines in the 1990 farm bill.

Organic Certification

For the first time, national standards for agricultural products labeled organic are established, which will give consumers who wish to choose products produced organically the opportunity. Standards apply to production and processing methods as well as to permitted materials, product handling, and labeling. Organic

certification has not been defined as a food safety measure per se, but rather a marketing measure that would organize the existing chaotic conditions applying to "organic" products. A determined coalition of producer and consumer interests succeeded in winning the measure against the long-standing adamant opposition of the U.S. Department of Agriculture.

Pesticide Recordkeeping

This new measure requires certified pesticide applicators to maintain records for two years on the use of restricted pesticides. These records are confidential but can be made available for the use of federal and state agencies and health care personnel.

Cosmetic Quality and Pesticide Use

The 1990 farm bill includes several new provisions that reflect society's ongoing concerns about the safety of pesticide and agricultural chemical use in agriculture. The issue of grades and standards, particularly those that pertain to surface—or "cosmetic"—appearance, was raised by several prominent consumer and environmental organizations during the 1990 farm bill debate. Their efforts resulted in a mandate to undertake several research projects to investigate the extent to which grades and standards, both voluntary and in conjunction with marketing orders, provide an incentive toward excessive pesticide use. The hypothesis is that cosmetic standards impede those producers attempting to reduce pesticide (and fertilizer) use and adopt alternative farming practices. Also mandated under the legislation were three two-year studies to evaluate marketing and education programs to provide consumers with choices of, and information about, commodities produced with alternative production processes. Whether these studies will be carried out by the U.S. Department of Agriculture and what they might lead to remains to be seen. Senator Dole amended the farm bill so that the numerous studies included in the 1,000-plus pages of the bill could be reduced to twelve and, reportedly, the cosmetic standards study currently is not on the short list.

In addition, the legislation permits citizens to petition the USDA for changes in grade standards. Previously, only the food marketing industry had standing for these purposes.

Country-of-Origin Labeling

Title XIII (fruits, vegetables, and marketing) contains a requirement to operate a two-year pilot program labeling products by country of origin.

Research

Research in general is treated fairly generously under the farm, appropriations, and budgeting bills. Agricultural research and extension programs are authorized for five years. The bills gradually increase funding authorization for USDA competitive research grants from \$70 million to \$500 million annually. The farm bill authorizes \$40 million annually for low-input research activities, \$20 million for integrated resource management research, and \$20 million for educational activities to extend practices to agricultural producers. Again, the differences between authorization and appropriation can be vast. Some suggest that an annual increase in competitive funding of about \$50 million is likely.

The GATT and Consumers

One goal of the GATT negotiations on agriculture was the "harmonization" of sanitary and phytosanitary standards internationally. Although it is extremely unclear at the time of writing whether any positive accord will result from the GATT, it is worth noting that some progress was made toward establishing a better framework for addressing trade disputes emanating from unlike national food safety and animal and plant health standards. Some agreement was reached to consider the scientific basis for food safety standards, and in so doing to provide a greater role to the three principle international food standards organizations. At this point, few countries are likely to agree to an international scientific court passing binding judgment in trade disputes, however.

Conclusions

Certain provisions of the farm bill respond to consumer and public concerns related to food safety and quality and the environment. Provisions that set stricter environmental compliance measures and penalties than previously (discussed in Antle's paper), reinforce the "green" theme of the farm bill. All in all, the bill moves agriculture and the public policy agenda farther along a road toward greater environmental responsibility and an examination of some of the unintended consequences of farm and marketing programs, grades and standards, and traditional research priorities. However, in the main, the farm bill retains much that is business as usual.

Several significant measures for consumers are not included in the 1990 farm bill. Some were passed separately, such as an extremely important nutrition labeling bill (P.L. 101-535 passed 8 Nov. 1990) and a nutrition monitoring bill (P.L. 101-455). Others remain unfinished business for the next Congress, including seafood inspection, FIFRA reauthorization, and the possible reintroduction of "circle of poison" legislation (see Natural Resources Defense Council).

Farm Policy Reform and the Environment

John M. Antle

U.S. farm policy in the 1980s was marked by three significant developments: the international farm policy reform movement, the active participation by environment interests in the writing of the 1985 and 1990 farm bills, and the federal budget constraint. These developments raise new questions for farm policy. What are the environmental implications of domestic and international farm policy reform? Can both agricultural and environmental policy objectives be met in one piece of legislation? How does the federal budget constraint affect the feasible set of policy options? The goal of this paper is to outline an analytical framework that integrates technological, economic, and political factors for analysis of agricultural-environmental policy and to draw some preliminary conclusions about the environmental implications of the 1990 farm bill and trade liberalization proposals in the GATT negotiations.

Goals, Tools, and Tradeoffs

The principal goal of farm policy is to increase the welfare of farm interests using the available menu of policy tools, including production quotas, price supports, and acreage limitations. Producer welfare $PS(y)$ is defined as a function of output y and is measured as producer surplus. Absent market distortions, agricultural policies generate tradeoffs between producer welfare and the welfare of other groups in the economy, including consumer, taxpayer, and environmental interests. Let consumer/taxpayer welfare $CST(y)$ also be defined as a function of output y . CST can be measured as consumer surplus plus the total economic cost of taxation including dead-weight losses. For a given set of market demand and supply functions, $CST + PS$ is maximized at the market equilibrium output y_e . At all output rates greater than or less than the market

equilibrium output y_e , $CST(y) + PS(y) < CST(y_e) + PS(y_e)$, as shown in quadrant 2 of figure 1.

The goal of environmental policy is to increase the welfare of environmental interests, measured as willingness to pay for environmental quality. This component of social welfare is referred to here as environmental surplus and is assumed to be an increasing concave function $ES(EQ)$, where EQ measures environmental quality, as shown in quadrant 4 of figure 1. EQ is assumed to be a decreasing, convex function of farm output y , as in quadrant 3 of figure 1. EQ embeds the physical and technological relationships that translate production activity into changes in environmental quality through erosion, water contamination, and so forth. The EQ function shifts according to the efficiency of pollution prevention technology. This is a stylized representation of the relationship between production and EQ ; a more realistic representation would account for the heterogeneity of the physical environment at a disaggregate level of analysis (Antle and Just).

Let the curve in quadrant 2 represent the hypothetical case in which output is set costlessly by government fiat. The result is the efficient set OEC plotted in quadrant 1 of figure 1. Point E in quadrant 1 of figure 1 represents the market equilibrium where $CST + PS$ is maximized; ES is maximized at point C where output is zero. Actual policies that are not fully efficient generate points inside OEC . The area BEC contains all points corresponding to policies that reduce output below y_e . The area OEB contains all points corresponding to policies that increase output above y_e .

Policy Efficiency and Policy Reform

Policy reform can be defined as a movement toward more efficient policies. There has been much attention devoted to the question of efficient policy choice (Becker, Gardner, Tullock). This is a central issue in policy reform because inefficiency is the *raison d'être* of policy reform.

John M. Antle is an associate professor, Department of Agricultural Economics and Economics, Montana State University, and a University Fellow at Resources for the Future.

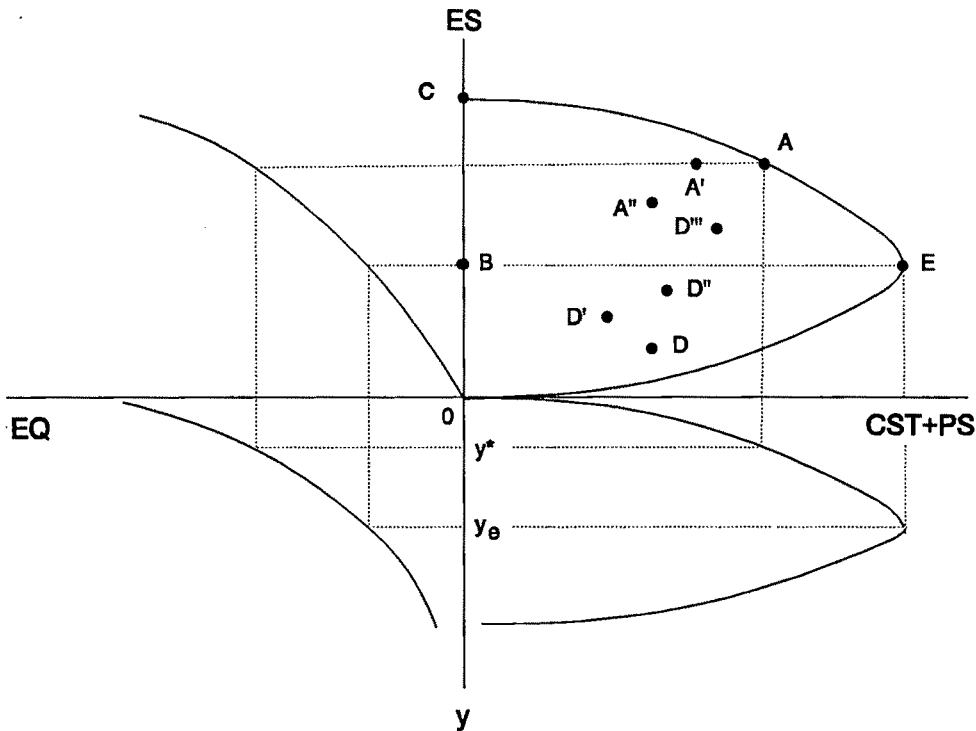

Figure 1. Welfare tradeoffs of agricultural policies

The socially efficient output level that maximizes aggregate welfare $CST(y) + PS(y) + ES(EQ(y))$ must satisfy $(CST' + PS')/ES'EQ' = -1$; that is, it will correspond to the point A on the efficiency frontier OE and an output level $y^* < y_e$. If income transfers to farmers are desired, lump-sum subsidies are the most efficient policy, assuming that the deadweight cost of taxation is less than that from other forms of intervention. If such subsidies were accomplished while holding output at y^* , the result would be a point such as A' in quadrant 1, where the difference $(A - A')$ measures the deadweight cost of taxation from the lump-sum transfer. The use of a production subsidy that increased output would reduce ES and entail higher deadweight losses and thus result in an even less efficient outcome such as point A'' .

A point like A'' is Pareto inferior to a point like A' , and it is tempting to conclude, as Becker does, that the political process should gravitate toward policies that are relatively efficient. Yet, relatively efficient subsidies, such as "decoupled" payments, are vigorously opposed by farm interests apparently because of their transparency. There is considerable evidence to show that many inefficient policies are used and persist over long periods of time in the United States

and elsewhere (Anderson and Hayami; Sturgis, Field, and Young).

There is, however, disagreement in the literature over the efficiency issue. This is a significant question for policy analysis because the prevailing paradigm of agricultural policy analysis is based on Pareto-efficient policy rankings derived from a welfare function or policy preference function (e.g., Rausser and Foster). The parameters of these functions are specified to reflect the political weights attached to competing interest groups. There are several reasons why policy rankings generated in this way may be erroneous. A potential Pareto improvement often is not politically feasible because the potential Pareto comparison of welfare gain does not account for political gains and losses to the politicians who make the policy choice (Antle and Johnson). The political process may prefer inefficient policies that obscure their redistributive effects (Tullock). And transactions costs in the political market may forestall efficient political trades.

The 1985 and 1990 Farm Bills

The conservation provisions of the 1985 farm bill—the CRP, sodbuster and swampbuster, and

conservation compliance—illustrate the growing influence of environmental interests in agricultural policy. In relation to figure 1, the 1981 farm bill was designed to support prices and expand output, thus putting U.S. agriculture at a point such as *D* in quadrant 1 of figure 1. The environmental lobbies were not able to eliminate all output-increasing aspects of farm programs, although the 1985 act did decouple target prices from variable production decisions by basing deficiency payments on program yields rather than actual yields. The 1985 act also had supply control provisions including the acreage reduction programs and the conservation programs. The CRP also transferred income to farmers, making it politically acceptable to both farm and environmental interests. Starting from point *D* in figure 1, this combination of policies moved the economy in a northwest direction to a point such as *D'*, raising environmental quality to some degree at the expense of consumers and taxpayers. While the 1985 farm bill did yield some environmental benefits, it is highly inefficient because it contains both output-increasing and output-reducing programs that work at cross purposes.

As the 1985 act was implemented its flaws began to become apparent. From an environmental point of view, the CRP was not efficient at improving environmental quality because its design did not target the most damaging erosion. As environmental interests focused more on potential chemical contamination of food and the environment, the inconsistencies between the output-increasing aspects of farm programs and environmental objectives were recognized. A related problem with the 1985 act, from the environmental point of view, was that the farm program participation rules limited a farmer's ability to rotate crops, thus possibly increasing the use of fertilizers and pesticides (National Research Council).

Another major problem with the 1985 act was that while it decoupled the target price from variable production decisions, it also transferred financial risk from farmers to the federal government by maintaining high target prices while reducing loan rates. The result was a program cost of some \$26 billion in 1986. The costs declined to about half that amount in 1988 and 1989 because of the higher market prices caused by the droughts in those years but remained high by historical standards.

Environmental interests were expected to be more influential in the design of the 1990 farm bill. A variety of proposals were put forward

early in the year, including better targeting and expansion of conservation programs (Center for Resource Economics et al.). Several factors diminished the environmentalists' influence, however, including disagreements among themselves over an agenda and the political strength of the farm lobbies in a year when all members of the House were up for reelection.

Early in 1990 the administration proposed to improve the economic and environmental efficiency of the commodity programs and reduce their budget cost by allowing farmers to plant nonprogram crops on their program base. Farmers would retain those acres in their program crop base but would not receive subsidies on those acres. This planting flexibility or triple base proposal was initially rejected by many members of Congress and farm interests apparently because, in their opinion, it transformed deficiency payments into politically unacceptable decoupled "welfare" payments. Planting flexibility was also opposed by some commodity producers who expected to be affected adversely as program participants diversified their production.

Environmentalists also sought a variety of regulations on land use and management practices, including tighter pesticide regulations and chemical recordkeeping requirements. These proposals were generally opposed by farm lobbies. Also contentious in the 1990 debate were the issues of wetlands conservation introduced in the 1985 act. Environmentalists felt the provisions were not being enforced and wanted them strengthened. Although this position was strongly opposed by farm interests, the environmentalists' position was strengthened by the president's campaign promise of "no net loss" of wetlands.

Without political pressure to reduce the budget costs of the farm programs, it is likely that the commodity and conservation provisions of the 1990 farm bill would have been very similar to those in the 1985 act, with somewhat expanded and better targeted conservation programs. Although the budget constraint imposed by the Gramm-Rudman-Hollings law imposed discipline on the options being considered during the first half of 1990, few anticipated the autumn budget crisis and the agreement between the administration and Congress to reduce farm program costs by an estimated \$13–\$15 billion over five years. This outcome favored the administration's farm bill proposal, as it precluded substantial expansion of the CRP or other costly conservation programs, and made the

administration's planting flexibility proposal politically feasible. The major budget-cutting provision of the bill thus became a mandatory 15% triple base. This outcome represents an increase in the economic and environmental efficiency of the farm programs. In terms of figure 1, U.S. agriculture will move from a point like D' to one like D'' as this policy is implemented.

The GATT and the Environment

At the time of this writing, it appears unlikely that a substantial measure of trade liberalization will be part of any final Uruguay Round agreement. This is unfortunate, as a reversal of the past ten years' trend toward agricultural protectionism would have been a significant accomplishment. A GATT agreement for agricultural trade liberalization would offer both problems and opportunities from an environmental point of view.

The key issue for environmental interests is whether trade liberalization would cause the United States to expand production in ways that will be environmentally damaging. Reduced export subsidies should cause world commodity prices to rise, encouraging production. But under a more market-oriented regime, only relatively productive land should be cropped. Environmental efficiency could be increased even as output increased if economically marginal lands are also the most environmentally sensitive. Thus, trade liberalization through a GATT agreement could bring about increases in both economic and environmental efficiency, corresponding to northwesterly movement from point D'' to a point like D''' in figure 1.

Economic and environmental efficiency also could be increased through the opportunity to redesign domestic subsidy programs (OECD). The GATT objective to decouple domestic subsidies from production could be made politically palatable to some farmers by converting price supports and deficiency payments into subsidies decoupled from production but linked to environmental objectives such as soil conservation, preservation of wildlife habitat, and reduced chemical use. This change in program design would face political difficulties, however. It would distribute program benefits differently than the existing programs, would not be attractive to agribusiness interests who favor output-expanding policies, and would be susceptible to budget pressures.

Trade liberalization makes some other aspects of environmental policy more difficult. Environmental regulations, such as restrictions on fertilizer and pesticide use, are likely to reduce the international competitiveness of U.S. farmers. Another difficult issue is harmonization of sanitary and phytosanitary regulations. U.S. environment interests oppose an agreement that would allow weaker food safety standards than current U.S. law.

Conclusions

Theories of government behavior suggest that policy reform will come incrementally unless there are substantial changes in political institutions and the influence of interest groups. They also suggest that when economic and political circumstances do change, there are opportunities for policy reform—policy changes that accomplish policy goals more efficiently.

Looked at from this perspective, the 1990 farm bill and the GATT should not be expected to be a "big deal." The degree of liberalization sought by the United States and the Cairns Group was not to be expected, as there is no dominant political constituency in the United States or among the GATT countries demanding policy reform to that degree. But neither do the 1990 farm bill or the GATT negotiations represent "business as usual." Although some of the most inefficient and inequitable aspects of domestic and trade policies still remain to be reformed, in some significant respects both the 1990 farm bill and the GATT present opportunities for increased economic and environmental efficiency. As such, both the 1990 farm bill and a possible Uruguay Round agreement can be regarded as positive developments in the evolution of agricultural policy design.

Special Interests and the 1990 Farm Bill

B. Delworth Gardner

Antle and Kramer have written useful papers. Antle's contains an innovative analytical framework that is helpful in interpreting the changes in farm legislation discussed in both papers.

Antle's social welfare function that includes taxpayers, consumers, agricultural producers, and environmental interests takes us a long way toward understanding the package of agricultural policies that have emerged in recent years. Other interests exist, to be sure, such as foreign producers and consumers, and they too are active in our political arena. The crucial question, however, is who really counts in determining the final outcome of a given bill? My interpretation of the evidence is that domestic producers have the heavy political weapons, the metaphor of nuclear bombs comes to mind. The environmental interests have a tank or two and taxpayers and consumers perhaps a Molotov cocktail. Time after time during congressional debate on the 1990 FACTA bill, amendments that would have advanced consumer and taxpayer interests were beaten back by committee members who were loyal supporters of producers. Thus, Antle's statement that "the principal goal of farm policy is to increase the welfare of farm interests" is more valid than is implied by his model or explicitly stated in his discussion.

Kramer's long list of consumer interests promoted in FACTA cannot convincingly be used as evidence for dominating consumer power since almost all of them do not constitute a threat to producer wealth and income positions. Little political conflict is likely when a change in policy enhances the welfare positions of both parties. It is when some gain occurs at the expense of others that we discover who has real political clout.

Environmental interests did achieve something of a breakthrough with the CRP, sodbuster, swampbuster, and conservation-compliance provisions in the 1985 FSA bill. However, given inelastic demand curves facing producers,

the CRP can hardly be described as inimical to producer incomes, especially considering the direct transfer to producers of about \$55 dollars per acre placed in the reserve and the 50% cost-share provided by the government to establish plant cover. On 30 October 1990, Secretary Yeutter announced that fiscal year 1991 payments to about 330,000 producers participating in CRP would be \$1.6 billion dollars, or an average of \$4,848 per participant. This amount is not an insignificant reward for their participation.

Sodbuster and swampbuster provisions have clearly been onerous as well as inequitable to producers, given that all program benefits could be withheld from violators, and luck largely determined whether or not a particular farmer happened to be located on environmentally sensitive land. Consistent with my thesis of producer power, the Congress responded to these concerns in the FACTA by providing numerous exemptions to the penalties mandated in the FSA. I am not arguing that these exemptions necessarily injure consumers and taxpayers or that they even represent inefficient policy. But they are hardly what environmentalists and conservationists desired.

Antle points out that deficiencies in the environmental provisions of the 1985 act soon became apparent, and that better targeting of the real environmental problems is the remedy. Agreed. However, Congress has never been willing to tightly target agricultural programs, whether they be deficiency payments, credit programs, disaster payments, or conservation programs. Even the food distribution benefits discussed by Kramer have often gone to "unintended" beneficiaries. The reasons are obvious: the goal of every member of Congress is to maximize the benefits conferred on those to whom he/she is politically beholden. The result is a broad distribution of program payments and benefits across the demographic and geographic spectra.

The FACTA appears to mandate bold new initiatives in protecting wetlands and water

B. Delworth is a professor of economics, Brigham Young University.

quality. The voluntary water-quality program hopes to enroll 10 million acres of farmland through 1995. But, of course, landowners will be paid to implement water-quality plans. And, of course, cost-share payments for wildlife and wetland preservation are also authorized. In fact, the FACTA suggests that, if necessary, the government might pick up the entire cost of the wetland and land-easement initiatives. So, it is business as usual after all. Just as was the case with CRP, these new programs are sure to be utilized for income transfers to participants that are not justified by environmental gains and economic-efficiency benefits.

FACTA mandates that CRP acres may be targeted for water-quality and other environmentally sensitive problems in addition to soil erodibility. Further, highly erodible land criteria have been tightened and marginal pasture land can now be eligible for the CRP under specified conditions. While all of these environmental features of the new act may produce some benefits, they also will give more political constituents a claim on the budgetary resources of the government. I predict that an even greater proportion of the government's budget will be politically allocated rather than targeted to the most critical environmental problems. Congressional pressures will be mounted for a watering down if not an evasion of those provisions that cut into producer profits.

Antle points out that Becker has argued that income transfers to producers will be done in ways that minimize deadweight efficiency losses.

Decoupling of payments from production decisions has many efficiency and environmental advantages and thus would reduce deadweight losses. However, less than 10 million acres of land have thus far been idled in the 0/92 and 50/92 decoupled programs as compared to about 30 million in the CRP and around 50 million in annual acreage set-asides. So much for efficient transfers! But why? Because producers have the political clout to get their transfers built into support prices, acreage allotments, and internal and external quotas where the payments are largely hidden from consumers and taxpayers.

FACTA has extended the marketing loan to oilseeds and possibly to wheat and the feed grains to guarantee that American exports are competitive. The budgetary costs with the taxpayers footing the bill could be enormous if the EC continues to subsidize exports, keeping world market prices low. The implications for the environment are unclear depending on the quantities and locations of acreage that is cropped and the incentives to use chemicals.

The triple base option gives farmers more planting flexibility in maintaining program crop bases than was available previously. As Kramer points out, this will probably result in more oilseed production and lower consumer prices for cooking oil and perhaps slightly lower livestock prices. But this could be offset by higher market prices for the grains which are displaced. Kramer seems to have it about right when predicting only a slight impact on consumers. Too bad we cannot say the same for taxpayers.

The 1990 Farm Bill and the Uruguay Round: Discussion

Daniel A. Sumner

The papers by Runge, and Rossmiller and Nugent review some major U.S. commodity policy changes of the last year (the 1990 Food, Agriculture, Conservation and Trade Act and the 1990 Budget Reconciliation Act). They then consider the major prospective policy change for international agriculture, the still-evolving Uruguay Round of multilateral trade negotiations under the GATT. This discussion follows the same path, and the main objective is to clarify some points raised in the two papers.

Most of the Runge paper consists of speculation on the politics of the process of creating the 1990 farm legislation or on the internal motives of the individual actors. But every participant or observer will have a different set of impressions. For example, from my perspective it seems clear that much of the core of the Administration Green Book was included in the final act. Instead of continuing in this vein, let us turn to the results for commodity policy.

For target price commodities (grains and cotton), payment yields were kept frozen for the next five years and effective loan rates were raised slightly but kept well below the range likely to provide a floor to market prices. Keeping these features of the 1985 act avoided a return to the major distortionary aspects of earlier programs. The innovation of the 1990 act was that the budget reduction (of some \$11.2 billion in projected commodity program spending over five years) was achieved in ways that should enhance the economic performance of the sector. Outlays were reduced by reducing the base acres eligible for deficiency payments by 15%. Under the new programs, even for program participants, the anticipated market price is the relevant supply price for marginal acreage decisions among program crops and oilseeds. With frozen program yields implying that market price is the relevant supply price for producers on the intensive mar-

gin as well, target price programs are substantially less distortionary than just five years ago. Farmers face market prices for all marginal production decisions. Further, the provision of the 1990 legislation that protects an additional 10% of base if planted to alternative crops allows more short-run supply response to market conditions by eliminating the potential capital loss of valuable base for changing crops. Unlike the lowering of target prices in the 1985 act, the structure of the programs themselves was made more market oriented in 1990.

One of the major controversies in 1990 was over eliminating program payment eligibility for those associated with farms with large gross sales or for those participants with high net incomes. These and other targeting schemes were pursued most vigorously outside the agricultural committees. Targeting raises basic questions about the purpose of commodity programs. If they are really income maintenance programs for the deserving needy, then the distribution of payments is indeed odd (Sumner). Alternatively, if their role is to regulate markets as industrial policy, then perhaps direct payments to individuals is not the appropriate program structure. In the end, no targeting was enacted in 1990 and little progress was made in clarifying the issues.

Commodity programs without direct payments did not progress toward market orientation in 1990. In 1990 the legal details of U.S. sugar import program was changed in response to a GATT challenge from Australia, but this was done administratively and will likely have no significant effect on the economic operation of the program. Legislation left the sugar (and peanut) program mostly unchanged from 1985.

Dairy policy saw a clear move away from market orientation in 1990. The 1985 Food Security Act provided a formula that keyed support price changes to the level of government purchases of surplus production. The support rate came down after 1987 and was likely to continue a slow downward path with continued expected surplus for the next year or two. But the 1990 act severed the link to market forces and

Daniel A. Sumner is the Deputy Assistant Secretary for Economics, U.S. Department of Agriculture, and a professor, Department of Agricultural and Resource Economics, North Carolina State University.

froze the support price at the current \$10.10 per hundredweight. The result will almost surely be large surpluses and outlays. Provisions for producer assessments and some unspecified suggestions for supply controls are what the legislation offers to stem the anticipated milk glut.

One provision of the dairy assessment scheme should be highlighted for its perverse implications. For the initial 5¢ per hundredweight assessment (scheduled to increase), dairy producers who do not increase their output from the previous year will have their assessments refunded. To qualify for a refund requires no growth, and being just one pound over the no-growth level requires payment of the full assessment. Consider the producer who sold 15,000 hundredweight at \$12 in 1991 and faces a 20¢ assessment for 1992. In this case, if she sells 15,001 hundredweight at \$12 per hundredweight in 1992, her net of assessment receipts will be \$2,988 less because of that last hundredweight of milk. For a 10% expansion the marginal net price for the last 150 hundredweight is not \$12 or \$11.80 but \$9.80 and increases asymptotically toward \$12. The demand price facing each producer has a discontinuity that implies an effective choice between a large expansion or no expansion at all. Young producers are penalized as are those with improving efficiency or other incentives to expand. The winners are those who are already well established and secure, though for all producers the incentives for herd improvements and other efficiencies are reduced.

The Uruguay Round

The Uruguay Round of trade negotiations was still underway in late December 1990, and the

months between the writing and printing of this discussion should resolve many of the uncertainties about the outcome of the Round. In this context perhaps two points are useful.

First, in the realm of reasonable outcomes for agricultural trade, our analysis at the U.S. Department of Agriculture (USDA) indicates no additional internal support reductions (above what was accomplished in 1985 and 1990) for the target price commodities in the United States (except perhaps for rice). The United States has made major cuts in internal production-related support levels since 1986, and the payment base reductions and other changes in 1990 are larger than other countries have been able to match. By suggesting further reductions in deficiency payments are necessary in a GATT agreement, Runge has simply not analyzed the proposals carefully.

Second, the set of outcomes based on the Hellstrom proposal in Brussels includes options that can have clear, measurable benefits for U.S. agriculture and trade. Rossmiller and Nugent are overly pessimistic that trade gains are not in the set of a potential compromise. Even a 30% reduction in European Community subsidized exports over five years would raise grain and other commodity prices substantially and provide new market opportunities for the competitive exporters. This is clearly on the path to bringing discipline to agricultural trade and should be enough to garner the support of commodity interests and economists alike.

Data Needs to Assess Environmental Quality Issues Related to Agriculture and Rural Areas

Jerald J. Fletcher and Tim T. Phipps

The assessment of environmental quality problems and the design and economic evaluation of alternative federal, state, and local policy strategies to address environmental issues require complex analyses which must address the underlying physical, biological, social, and economic processes. The study of environmental problems is thus inherently multidisciplinary and should involve the physical, biological, and social sciences. Unfortunately, the multidisciplinary nature of environmental issues has caused problems with the quality and general availability of the data necessary for appropriate analyses. While data have been collected in many areas to address discipline-specific problems, there has been little regard for the eventual need to coordinate analyses across disciplinary lines. As Portney points out, this lack of coordination in data collection is reflected in the often Balkanized system of data collection among federal statistical, research, and action agencies.

The activities of the Economic Statistics Committee (ESC) of the American Agricultural Economics Association (AAEA) highlight the need for the appropriate data to analyze both the causes and consequences of environmental problems as well as the set of alternative policy solutions that have been or may be proposed to alleviate such problems (Bishop and Ervin).¹ This paper reflects the continuing concern of the ESC with these issues.

Jerald J. Fletcher and Tim T. Phipps are associate professors in the Division of Resource Management, West Virginia University.

This is Scientific Article No. 2281 of the West Virginia University Agriculture and Forestry Experiment Station.

Helpful comments by Virgil Norton on an earlier draft of this paper are acknowledged.

The ESC sponsored a survey during 1988–89 followed by a workshop, "New Directions in Data, Information Systems, and Their Uses," prior to the 1989 AAEA annual meetings in Baton Rouge, LA, to develop a comprehensive picture of the current and future data needs of agricultural and rural social scientists, (Hushak, Chern, and Tweeten).

This paper builds on previous discussions of the methodological approaches to, and the associated data needed for, the study of environmental problems. The primary focus is on the underlying issues that must be resolved in this area, not an exhaustive review of current data availability nor a repeat of the common call for additional data and data collection efforts. The promise of relatively recent advances in computer methods (primarily geographic information systems—GIS) for data development and analysis and the implications for future directions for empirical economic analysis of environmental problems are discussed. There is also discussion of a variety of separate, but related, issues that pertain to environmental data needs. Finally, we derive implications from the discussion that can guide current and future data-gathering efforts to aid in the analysis of environmental problems and policies.

A Framework for Assessing Agriculturally Related Environmental Data Needs

To gain a better perspective on the data needs problem, it is useful to consider the framework in which the data are to be analyzed. Just and Antle develop a conceptual framework that considers interactions between agricultural and environmental policies. The framework is based on a model that shows that farmers' production decisions generate a joint distribution of output, input, environmental attributes, and pollution. Using their framework, they argue for the need to know the joint spatial distribution of both physical and economic factors in order to analyze the economic and environmental consequences of agricultural and environmental policies. They conclude: "Our analysis points to the kinds of data that are needed to make valid in-

ferences. Statistically reliable field-specific production data and environmental data would make possible measurement of key parameters (such as the correlation between production decisions and environmental attributes of land) that are needed to assess the aggregate relationships between agricultural policy, environmental policy, and the environment" (p. 202). We second Just and Antle's call for greater coordination of the research and data-gathering efforts of the various disciplines involved in the analysis of environmental problems and policies. The need for information on the joint distribution of economic, social, physical, and biological parameters should be recognized. We would, however, like to discuss the implications of their conclusions for the further development of appropriate data and analytical methods.

In practice, the collection and analysis of data relevant to environmental policy problems does not, and should not necessarily, proceed only from the field level to the aggregate. The development of the appropriate data is a dynamic process that iterates between aggregated analysis of the data at hand and more detailed data collection based upon the results of prior aggregated analysis. Analysis of the additional data and the implications gleaned from further aggregate analysis may lead to another round of data gathering as well as, in many cases, redefinition of the policy problem or issue under consideration. That is, data needs are fundamentally related to the problem being analyzed; the problem defines the data needs, while the availability of data limits the problems that can be addressed. The Just and Antle framework should not be interpreted to mean that the availability of field-specific data is a necessary requirement for spatially detailed analysis; the development of such data is neither necessary nor economically efficient for many policy problems. As their framework makes clear, it is the correlation of relevant factors that is important. The level of detail necessary in the data collection that this implies largely will depend on the spatial and temporal correlation coefficients among the factors.

Geographic Information Systems

Geographic information systems (GIS) have the potential to greatly increase the usefulness of existing data in the analysis of environmental problems. A geographic information system is a combination of computer hardware and soft-

ware designed to collect, manage, analyze, and display spatially referenced data. The GIS approach to handling vast amounts of data while preserving spatial detail has been enthusiastically received by many of the scientific disciplines and agencies working in areas germane to environmental issues. Examples of GIS applications include such diverse activities as describing and managing natural resources such as forests, soils, water, and minerals; use by utility companies to plan routing and service areas; application to the work of local area planning committee, tax assessors, zoning boards, surveyors; and the list could be extended. Because of the large number of observations and the complexity of the relationships among the data points necessary to provide spatially detailed information on resource characteristics that vary significantly over space and/or time, computer applications of GIS have traditionally been expensive and reserved for relatively high-powered mainframe systems with large amounts of data storage. Recent advances in the computing power of personal workstations has made computer-intensive data analysis such as GIS cost effective.

Economists, however, have not yet widely adopted GIS approaches nor adapted empirical economic analysis to utilize the potential benefits of GIS. While GIS and related technologies are making it possible to generate, manipulate, understand, and disseminate information about the world far more broadly and pervasively than has been possible with previous technologies, economists have often seen only the final results—the maps or other graphic displays of physical phenomena. Such a picture hides the individual features of the many thousands of data points of which it is composed. GIS may be incorrectly perceived as merely a useful tool for creating maps, not as a separate tool to be used in spatial analysis.

A discussion of the potential that GIS hold for strengthening economic analyses may open new research paths in economics. GIS can significantly improve our ability to analyze environmental problems using conventional approaches by significantly improving the quality and the quantity of available data. In addition, we believe that GIS will open new avenues of empirical analysis based on spatial statistics and result in the development of novel and innovative approaches to policy analysis. The first issue involves new tools for old questions, while the latter may be summarized as new questions arising from new tools.

Using GIS to Facilitate the Use of Available Data

Numerous government agencies devote a considerable portion of their budgets and available manpower to collecting information on the world in which we live. Environmental data (or data relevant to the analysis of environmental problems) are collected by diverse agencies in many departments. For example, in the Department of Commerce, the National Oceanic and Atmospheric Administration has extensive spatial and temporal data on weather patterns and climatic conditions, while the Bureau of the Census develops extensive information on many demographic and economic aspects of our industrial society. In the Department of Interior, the Geological Survey has data on ground and surface water quantity and quality, on geologic formations, chemical compositions, and many other measures of interest to specific problems; the Bureau of Land Management maintains information on portions of the public lands, and the Fish and Wildlife Service has data on wildlife and fishery habitat and abundance as well as recreational use. In the Department of Agriculture, the Soil Conservation Service has detailed information on soil characteristics and related data for private lands; the National Agricultural Statistics Service (NASS) develops information on agricultural inputs, production, and related items; and the Forest Service has information on recreation use, fisheries, and many other aspects of public forest lands besides those directly related to timber production. The Environmental Protection Agency has extensive data sets on pollution sources. The National Aeronautics and Space Administration and the Departments of Defense, Energy, and Health and Human Services all collect and maintain data that may be useful in analyzing specific environmental issues. This list reflects the diverse nature of the data useful in the analysis of environmental issues. It could be extended significantly, but the point is clear: the sources of relevant data are numerous and diverse. (See Yarden et al. and Garkey and Chern for specific details on data availability.)

The various collections of data for analyzing environmental issues are quite diverse, and published statistics are of such an aggregate nature that they often are not useful in developing insight into the spatial correlations and complex interactions between the physical resource base, natural phenomena, and man's activities that result in environmental problems. The raw data on which such statistics are based, however, often

are of sufficient detail and contain the temporal and spatial reference points necessary to develop linkages between disparate data sets. Such data can be used in the analysis of problems not contemplated by the original collectors of the basic data. In many instances, however, while the basic information may be included in the raw data, the form and method of storage varies so greatly across agencies and among data sets that systematic joint analysis of the disparate data sets has been difficult and costly at best and often virtually impossible from a practical perspective. Recent developments in computer hardware and software may provide a key to better data utilization if institutional and legal constraints can be overcome.

Much of the information available on the resource base has yet to be included in the economic analysis of environmental problems, although aggregate statistics drawn from the data are often used. In many cases, the information on resource characteristics has been reported as maps, often with the information summarized in a series of contour or "iso-value" lines. Examples include average rainfall, elevation, precipitation, soil type, temperature, habitat, and so on. The ranges reported are related to the scale of the map and the properties underlying the spatial end, in some cases, temporal distribution of the characteristic of interest. Using such information in even a simple economic analysis has traditionally required a large investment of both time and effort in the development of a data set that reflects the attributes of the resource characteristic and is of a scale or level of aggregation suitable to the problem under consideration.

In recent years many of the older maps have been stored in electronic format as part of a GIS system, and newer maps are often a visual depiction of information stored in digital form. If the information is available in a suitable GIS format, summary statistics relative to a single resource variable or combination of variables that includes spatial references can be developed with relative ease. GIS systems can also be used to combine synthetic data, for example estimates of nonpoint pollution loading from agricultural lands produced by simulation models (perhaps based on observed parameters of the resource base and hypothetical or observed management parameters contained in a GIS), with observations on point sources to obtain overall estimates of an environmental quality parameter such as BOD in ambient water. The data requirements for the sound analysis of environmental issues may be best met from nontraditional sources.

Thus, current GIS systems can increase the number of data series available for conventional economic analysis if the economist knows about the relevant data and has access to it. With the increasing prominence of multidisciplinary approaches to problems that cut across traditional disciplinary boundaries, it is important that existing data originally gathered to support research in individual disciplines be catalogued and made accessible to others.

Using GIS to Develop Innovative Approaches to Economic Policy Analysis

Of more interest is how GIS and related technical developments in statistics may provide new paths for empirical analyses. As a profession, economists have concentrated on time-series analysis, the analysis of data that have temporal reference points but without spatial dimension. When the concept of space has been introduced in the analysis, it has usually been in a simple way, such as the way distance is introduced in travel cost models to measure resource price. While developments in spatial econometrics have been reported in the literature (see Paelinck and Klaassen for an introduction), applications have been primarily in the regional science literature and heavily dominated by Western European citations. The promise that GIS hold for the improved analysis of environmental problems rests largely on the ability of GIS to provide the foundation necessary to develop spatial autocorrelation functions and other measures of spatial correspondence that may be important in gauging the effects of environmental problems and alternative policies.

Issues Related to Environmental Data Needs

A number of specific issues are especially pertinent to the data needs for evaluating environmental problems. These include barriers to the accessibility of existing data, such as confidentiality, moves toward the privatization of data, the effects of nonmarket aspects of critical factors related to environmental quality, uncertainty in the data, and the appropriate level of reliability.

Barriers to Access

A number of difficult issues are related to institutional and legal barriers to data access. One

of the most pressing is confidentiality—an individual's right to privacy versus society's right to know. Confidentiality is particularly a problem with environmental data because of the need to preserve spatial detail in the analysis and often in the presentation of results. Confidentiality is often dealt with in other areas by making the data available only in an aggregated form. Unfortunately, as discussed above, aggregated data are often not useful in analyzing environmental problems. This issue will continue to receive attention from a broad spectrum of interests, and the final outcome is far from decided.

A second, but related, issue is duplication of effort. While duplication has traditionally arisen from lack of communication among those gathering the data; now it sometimes arises because of confidentiality constraints. If agencies are unable to share information because of confidentiality rules, both may gather the same basic information to meet their stated objectives even if additional burden is placed on respondents. Again, a tradeoff occurs between the benefits of privacy and the costs of duplication.

A third issue is the move toward privatization of data. For example, much of the remote sensing data is now obtained from SPOT, a for-profit corporation whose objective is to make money from the images collected. Another and more insidious problem is the move toward private distribution of data collected by public agencies. For example, various private companies market value-added products based on census data. While this is in many cases appropriate, if private provision of data leads to reduced public access to data, this seems to undercut the primary reason for public data collection efforts, the public good aspects of information, and the natural monopoly nature of data collection efforts.

Security and national defense comprise the fourth issue. The information available via remote sensing, satellite photography, and other modern technologies is of vital importance to national security interests and therefore is often classified. If made available to the general public, on the other hand, the information obtained by security and defense agencies could dramatically alter the information available for the analysis of environmental and resource issues.

Effects of the Non-Market Characteristics of Environmental Issues

As noted by Bishop and Ervin, many environmental issues involve actions or goods that are not traded on markets and cannot be measured

by observing market transactions. Analysis of environmental issues must, therefore, often rely on nonmarket techniques to measure economic benefits and costs. In many such cases, economists are left to collect the necessary information directly. Many of these nonmarket techniques, such as contingent valuation, utilize survey methods that are not generally part of the training of most economists (Bishop and Ervin). This need for greater training in nonmarket evaluation techniques was driven home by the level of attendance at the nonmarket benefit session at the Vancouver meetings in 1990.

Perhaps more important from a data perspective, the data generated as part of a nonmarket benefit study are often relevant only to the particular situation under study. The development of methods that would circumvent this problem could return large benefits. One possibility is to develop and specify models to evaluate nonmarket inputs and outputs that allow generalization of the estimated parameters to other regions and situations (Walsh, McKean, and Johnston).

In any case, economists cannot look to our fellow researchers in other disciplines to solve the problem of valuing nonmarket goods. Valuing environmental amenities, damages, and other nonmarket goods belongs to the economist. The basic understanding of these nonmarket values is not yet sufficient to allow for broad collection of appropriate values by a statistical agency. However, it is important to use the information gleaned from specific studies to develop methodologies that will complement the information available on the resource base. The result will better guide policy development and evaluation.

Uncertainty in the Data

Bishop and Ervin also note a tendency for greater uncertainty associated with natural resource and environmental data than with most data used in other areas of research. Each step in what is often a complex chain of interactions that result in environmental problems has, at best, some uncertainty associated with expected outcomes. As these steps are combined, the uncertainty may be compounded. However, because coefficients and/or data developed by other disciplines are often entered into an economic analysis as nonstochastic terms, the true nature of the uncertainty in a particular problem may be obscured.

Uncertainty is associated with the location and behavior of a pollutant in the environment. For

example, it is often necessary to know how pollutants are transported spatially, potentially a three-dimensional problem. In addition, there is an added temporal dimension of decay or accumulation that depends on the environmental characteristics of each point in space (e.g., soil type) and time (e.g., temperature). Thus, uncertainty enters not only with location of a pollutant in four-dimensional space-time but also with the environmental attributes and chemical processes associated with each point. Locational and behavioral uncertainty is compounded by uncertainty of the effects. That is, not only is the level of pollution uncertain, but the environmental or health damages caused by the pollutant are often only partially understood. This uncertainty is compounded when the secondary effects from combinations of pollutants, intermediate compounds formed by the pollutant, or (once ingested) metabolites of the pollutant are considered.

The great complexity and uncertainty associated with the location, behavior, and damages of a pollutant mean that information is required from a wider variety of sources than is necessary for most problems analyzed by economists. Frequently, the available data were originally developed from samples fraught with problems of sample selection bias. That is, much of the available data is not based on random or stratified random samples but is, as noted by Bishop and Ervin, driven by particular problems, public complaints, or "hot spots." Typically, the available environmental data relevant to a particular problem will be a combination of randomly sampled data for certain regions, no data for other regions, and biased or "hot spot" data for still other regions. While data collected on a nonrandom basis contain less information than a well-constructed random sample, it does contain some information. The trick is to combine the available information so that the statistical integrity (or lack thereof) of each sample is preserved, and then to present the results in a way that accurately conveys the differing statistical reliability for each region.

Appropriate Level of Data Reliability

As mentioned earlier, the level of accuracy or reliability of the data needed is related to the problem under consideration. For water pollution from agricultural production, data at the field level or even lower may be necessary to predict accurately both the economic and environmental

effects of alternative policies if relevant field characteristics vary significantly. While this level of spatially detailed data would be ideal, it is not economically efficient or necessary to gather such data to analyze many issues of interest. While this level of detail would be needed if the policy were a centralized command and control program, most of the environmental problems related to agriculture are nonpoint in nature and not well suited to such policies. Policies that address agricultural nonpoint pollution are often handled more efficiently by a mix of centralized and decentralized decision making, with each level of decision requiring data of different reliability or scale of sampling.

Soil conservation policy provides a good example. As part of the National Resources Inventory (NRI) first conducted in 1977, data on soil erosion were developed that demonstrated that erosion problems are highly concentrated in a few regions of the country. This information spawned the policy problem of targeting soil conservation spending to those regions with the most severe soil erosion problems. While such targeting is more cost effective than not targeting, there is also high intraregion variability in soil erosion rates. Unfortunately, while the NRI is statistically valid at the major land resource area level, it is not detailed enough to determine the actual fields, or portions of fields, that require treatment.

The NRI, however, can be used in two ways to guide soil conservation policy. The first is to help policy analysts determine which regions of the country, and the characteristics of areas within each region, where it would be most efficient to gather the highly detailed data needed for field-level treatment. A second, and related, possible use is to serve as the first step in a multistage budgeting process, where the first stage is the centralized decision of how to allocate the soil conservation budget among competing regions and the second is the regionally decentralized decision of how to allocate regional budgets among farms. The third step is fully decentralized decisions made by individual farmers about how to allocate received soil conservation funds among competing techniques and fields. This step would necessarily require detailed knowledge of the resource base as well as characteristics of the farm firm, but attempting to use this information in the initial allocation stages may not be practical. It is still likely, however, that the information necessary for local implementation of any policy or plan will be much more detailed than that necessary to guide the formulation of national policies and guidelines.

Conclusions and Future Implications

We have not attempted to reiterate the lists of environmental data needs that have been put forward in numerous pleas for more data. While more data are needed—in some areas the information available is woefully lacking—there is a great need for consolidation and assessment of existing data to guide additional data collection efforts. While the need for additional data is obvious in many areas, in other cases the need could be filled, at least in part, by existing information housed in seemingly unlikely places. Many agencies have gathered considerable data on the resource base of the United States—we probably know more about our country's resources than any other in the world. However, much of this information is virtually inaccessible to those most interested even if they have managed, by some happenstance, to learn of it. We can only reiterate our perceived need for a clearing house for environmental data, a "Bureau of Environmental Statistics" as so ably stated by Portney.

Such a central agency for the collection, evaluation, and delivery of critical environmental information would provide a tremendous leap toward meeting environmental objectives. A central environmental clearing house could provide for combining data sets (perhaps individually confidential) from diverse sources in ways necessary for appropriate analysis while still maintaining the required levels of confidentiality and protecting the rights of the individual. Appropriately funded and supported, a central clearing house could coordinate data collection efforts, reduce duplication, and provide guidelines for a common data format.

Interdisciplinary communication on data collection and collaboration across disciplines on experimental design also are needed. While disciplinary studies may concentrate on particular aspects of a problem, a coordinated effort could develop not only discipline-specific data but add those data necessary for the results and conclusions to be assimilated in other research by other disciplines. For example, agronomic studies based on an experimental design that creates the data necessary for analysis of variance tests of alternative levels of a particular treatment may provide little insight into the tradeoffs and substitutions among inputs. Many such studies have not recorded the levels of factors held as controls within a particular experiment but necessary to make the results useful in understanding broader questions related to input controls and other factors of interest.

We would hope that current and future data-gathering efforts will result in an integrated approach to data collection and analysis that will allow for the compilation of the spatial and temporal correlation functions necessary to guide aggregation of site-specific studies to broader aggregates. Examples of such efforts are the crop-specific studies conducted by NASS in cooperation with the Economic Research Service (ERS), the Management Systems Evaluation Area (MSEA) projects that result from cooperative efforts among a variety of agencies concerned with environmental problems in agriculture, and the area studies anticipated by the ERS. While we cannot expect all data needs to be filled immediately, careful, coordinated planning of efforts now underway can significantly increase the effectiveness of such studies in shedding light on underlying data and aggregation issues.

Data Needs to Address Economic Issues in Food Safety

Tanya Roberts and David Smallwood

Invisible hazards and imperfect information held by producers, consumers, and regulators continue to make food safety a volatile issue that can disrupt markets and cause substantial losses to suppliers of agricultural inputs, farmers, marketers, and consumers. New and improved data are needed to assess risks, consumer demand, and costs of alternative private and public control strategies.

Food safety data were identified as a high priority by several groups. The 1989 Survey of Agricultural and Rural Social Scientists ranked "very important" data collection and dissemination efforts and gave "develop measures of food safety" a rank of seventh and "inventory of pesticide and herbicide applications" a rank of ninth (Hushak, Chern, and Tweeten). A report of the planning and budget subcommittee of the Experiment Station Committee on Organization and Policy (ESCOP), *Research Agenda for the 1990s: A Strategic Plan for the State Agricultural Experiment Stations*, rated "ensuring the safety and stability of consumer foods" as its first priority. The National Research Initiative Competitive Grants Program in the U.S. Department of Agriculture (USDA) added food safety to its list of program areas for funding in 1990, largely because of ESCOP's rating. President Bush proposed a major food safety initiative in 1989 with a large data collection component, and Congress appropriated funds in 1990.

Better data are needed on the incidence, severity, and economic dimensions of foodborne disease from microbial (bacteria, parasites, fungi, and viruses), chemical (insecticides, herbicides, fertilizers, animal drugs, environmental con-

taminants, food additives), and natural constituents (including biotechnology) in food.¹ No data source exists with definitive estimates of the number of illnesses caused by foodborne sources or the distribution of disease severities (OMB). The estimates in the literature suggest that microbial sources are causing from 6.5 to 33 million cases of foodborne disease annually and 9,000 deaths (Bennett et al., Garthright, Archer, and Kvenberg). Chemical sources of foodborne disease risk are less well characterized. A worst case EPA estimate suggests 6,000 cases of cancer annually (EPA 1987), while others have reckoned the risk to be much smaller (EPA 1990, Ames and Gold, Archibald and Winter). Economists can contribute to the food safety discussion by identifying data needed for economic analysis, estimating the social welfare costs of foodborne illness, and estimating benefits and costs of alternative control programs.

More Information Improves Social Welfare

The central food safety problem is lack of information. Consumers cannot look at a package of food and see either chemical residues or microbial contaminants. Food safety attributes are difficult for consumers to quantify even after consumption or "experience" with the product. For chemical residues the human health effects, such as cancer, may not be experienced for many years. For many microbial risks, consumers cannot correlate flu-like symptoms with food because the lag of days to weeks between food consumption and illness prohibits identification of the specific food or other source of illness. Thus, food safety attributes are not readily apparent either before purchase or after consumption of food.

Producers of risky foods do not have an in-

Tanya Roberts and David Smallwood are agricultural economists in the Food Policy Research Section, Economic Research Service, U.S. Department of Agriculture.

The views expressed in this paper are solely those of the authors and should not be interpreted as official policy of the U.S. Department of Agriculture.

Review comments are appreciated from Betsy Frazao, Lester Myers, and John Schaub, Economic Research Service; Peter Kuch, Environmental Protection Agency; Bev Fleisher, National Science Foundation; David Berkowitz, Food Safety and Inspection Service; and Bing Garthright, Food and Drug Administration.

¹ There are two emerging areas of data needs that we have not been able to address: biotechnology and natural toxic constituents. Ames and Gold believe that the human health risk from natural plant constituents is several times greater than the risk from chemical residues in foods.

centive to disclose risk information because they will make higher profits if consumers are uninformed. As Akerlof demonstrated, asymmetrical information about product attributes creates market failure.

Market forces not only disclose too little food safety information but also generate too little information. Basic research about food safety, such as developing risk assessment mechanisms or new tests to identify foodborne hazards, is underfunded because of its public good characteristics.

One could imagine that, even if the market did not disclose information optimally, private liability laws could provide the necessary incentives for firms to produce the socially optimum level of product risk. However, Viscusi demonstrated that tort liability does not work efficiently to redress health and safety problems in the marketplace because only a subset of the total harms are compensatable, and only risks which have discrete, easily traceable causes are handled well by the tort system. An efficient product liability system can sometimes remedy the disclosure of information problem but cannot solve the general lack of information problem.

Government subsidization of basic research and data collection often improves social welfare (National Academy of Science 1965). New food safety research and data collection can help to reduce uncertainty in decision making and reduce costs due to the misallocation of resources. For convenience, we distinguish data needs into two broad categories: physical/biological science data needs and economic/behavioral science data needs.

Physical/biological data are needed to quantify the underlying technical relationship in the production, processing, and marketing of agricultural commodities. In particular, this type of data is needed to establish how chemical and microbial contamination levels relate to production, processing, marketing, product quality, and health risks. Critical to the ability to obtain such information is the availability of tests for detecting chemical residues and microbial levels in an economically efficient way.

Economic/behavioral data are necessary to understand factors affecting the choices of market participants. To alter food production and handling practices to reduce foodborne risks, one must know something about the economic tradeoffs facing producers, processors, and consumers. For example, reducing chemical use on farms and in the marketing system requires knowing the impacts of pesticide, fuel, and la-

bor prices and alternative pest control strategies (such as alternative chemical pesticides, biological controls, product quality, crop rotation, weeding, and integrated pest management) on pesticide usage, productivity, and costs. Both physical/biological and economic/behavioral data have important economic implications for foodborne risk assessment and risk management. Decision makers, whether they be consumers, producers, or regulators, need to evaluate the economic consequences of alternative choices, and these choices depend in part on the underlying physical and biological relationships. Especially important is the recognition and measurement of risk "tradeoffs," i.e., how does the reduction of one source of risk affect exposure to other types of risk and what are the economic costs of this tradeoff?

Physical/Biological Data Needs

New data are needed to pinpoint the food safety hazards associated with the greatest social costs, more definitively identify the foods which are vehicles for these hazards, clarify where the hazardous chemicals or microbes are entering the food chain, and clarify the underlying physical and biological relationships of possible control programs.

Microbial risk assessment data are needed to better estimate the extent and range of human illnesses from microbially contaminated food because there is no consensus on how many cases of foodborne illness occur annually. Yearly, 400–500 foodborne outbreaks involving a total of 20,000 to 25,000 persons are reported to the Centers for Disease Control (CDC).² Recently CDC researchers published their "best estimate" of acute cases of foodborne microbial illness—6.5 million cases annually in the United States, of which 9,000 end in death (Bennett et al.). Researchers in the Food and Drug Administration have examined human illness data and estimated 33 million cases of foodborne illness annually (Garthright, Archer, and Kvenberg). None of these three estimates is universally accepted, and all omit some classes of acute illness (for example, most foodborne viruses lack identifying tests, although viruses are thought to be an important cause of foodborne illness). Also, complications and chronic conditions following

² About 60% of the organisms causing outbreaks are not identified (Centers for Disease Control, Bean et al.). The uncertainties in estimating microbial risks come from underreporting acute illnesses as well as complications following acute illness.

the acute foodborne illness, such as septicemia, arthritis, or cardiac dysfunction, may be difficult to associate with their foodborne cause (Archer 1984, 1985; Mossel).

The social costs of foodborne illness, using the cost of illness approach to quantify medical and productivity losses, have been estimated in the literature at \$4 billion to \$8 billion annually (Garthright, Archer, and Kvenberg; Roberts; Todd). The social costs of complications or chronic conditions following the acute infection may be more costly than the acute illness. For example, in one survey people with arthritis were willing to pay 22% of their household income to get rid of arthritis (Thompson). Roberts and Frenkel estimated that the acute illness costs of fetal exposure to *Toxoplasma gondii*, a common contaminant of pork, were dwarfed by the lifetime productivity losses, additional training costs,

and increased living costs for persons developing mental retardation.

Given advances in epidemiology and rapid tests identifying microbial pathogens, a superior tracking system for microbial risks could be established for use by regulators. The Centers for Disease Control now collects some of this data in a fragmentary fashion in its foodborne disease outbreak reports. Expanding the scope of CDC's efforts, linking it to data collected in other health surveys, and linking it more closely to food vehicles would improve the ability of FDA and FSIS to quantify foodborne disease risks and fashion regulatory programs to reduce human illnesses from foodborne sources (table 1). Particular attention should be given to strengthening identification of microbial foodborne deaths, both because of the importance of achieving a consensus on the number of foodborne deaths

Table 1. Data Needed for Estimating Microbial Health Risks

Data Need	Possible Solution	Likely Cost
Better recording of existing data	<ul style="list-style-type: none"> Expand CDC's passive laboratory-based reporting for 9 foodborne microbial pathogens to the 30 with tests. (Expanding the use of tests by state laboratories would increase costs more.) Expand CDC's laboratory-based reporting to make surveillance active in selected counties (sentinel counties). 	Around \$500,000/year Additional \$1 million/year Around \$75,000
Better demographic data on who becomes ill	<ul style="list-style-type: none"> Study various methods of making reporting active and estimate likely costs and benefits of increased identification of cases. 	
Increased knowledge about risk factors	<ul style="list-style-type: none"> Study individual susceptibility as well as food handling and consumption practices for people becoming ill and control groups who do not become ill. 	Around \$500,000/pathogen
Increased knowledge of disease severities	<ul style="list-style-type: none"> Increase the number of pathogens investigated in depth with surveys of people becoming ill from specific foodborne pathogens. 	Each survey may cost around \$100,000–\$200,000
Increased knowledge on deaths from foodborne sources	<ul style="list-style-type: none"> Expand the sentinel county survey to include all counties in the United States for a few selected pathogens to develop a solid baseline on foodborne deaths. Study improving the identification of foodborne deaths in the National Death Index by improving entry of laboratory test data, by revising the death certificate to specifically ask for laboratory data, etc. 	Around \$1 million/pathogen for passive surveillance, and much more for active surveillance Around \$300,000
Increased knowledge about hospitalizations caused by foodborne pathogens	<ul style="list-style-type: none"> Study improving identification of foodborne pathogens in the National Hospital Discharge Survey (NHDS) by 1) examining a sample of the 150,000 hospitalizations under ICD-9 "008-unspecified intestinal infections" to see if medical records contain laboratory data, 2) examining septicemia/bacteremia records for 1 year to determine if foodborne pathogens are involved, 3) estimating the cost of revising the face sheet for entry of NHDS data to include laboratory data and where sample taken (blood, stool, cerebrospinal fluid), and 4) comparing state systems. 	Unknown, but likely to be less than \$200,000/study
Quantification of chronic conditions caused by foodborne pathogens	<ul style="list-style-type: none"> Review the literature and estimate the likelihood that foodborne pathogens are important in certain chronic disease syndromes such as reactive arthritis, neurological disorders, cardiac dysfunction, food allergies, gastritis, kidney and liver dysfunction, etc. 	Literature review around \$100,000; original research more costly

and because of the high social costs associated with deaths.

Chemical risk assessment data are needed to identify and clarify the range and extent of human health risks. Assessment of chemical risks are influenced by four major factors: chemical usage levels, residue concentrations, potency/toxicity, and consumption levels. To compensate for limited data, scientists often make different assumptions in their analyses. Limited data can lead to dramatically different conclusions regarding the absolute risk levels and the relative ranking of sources of risk. Results from two studies are shown in table 2. The National Academy of Sciences (NAS) study estimates, using EPA risk assessment procedures, are often many orders of magnitude higher than the Archibald and Winter study. For example, the NAS study estimated that chlordimeform used on tomatoes increases cancer risk by 479 additional cases per million people over their lifetime. In

contrast, Archibald and Winter, using FDA residue data to indicate human exposure, estimate no increase in cancer risk from its use on tomatoes. The risk assessments in these two studies suggest vastly different regulatory concerns and strategies. Better and more standardized data and procedures are needed to clarify the actual risks involved.

EPA studies have not developed a consensus on foodborne disease risks. In 1987, the agency estimated the chemical residues on food caused no more than 6,000 excess cancer cases annually, a rank of third out of fifteen risks studied (EPA 1987). A more recent outside advisory panel study estimated the risks of foodborne chemical contamination to rank twenty-fifth out of thirty risks evaluated (EPA 1990).

Data needs for chemical risk assessment include more tests to assess the toxicity of chemicals. The NAS study used only twenty-eight of fifty-three suspected oncogenic pesticides be-

Source: Data are from Archibald and Winter.

Note: Because of limited availability of data, NAS assumed a worst case scenario that each pesticide was present on the approved commodities at the tolerance level. The NAS assumption implies that each pesticide was applied to every acre of every crop for which the chemical was approved and was used in its most intensive manner approved. While this assumption is useful in obtaining an upper bound on usage, it is unlikely to represent actual usage because application rates depend on a number of environmental and economic factors. In addition, some of the pesticides are substitutes for one another, making it unlikely that they would be used jointly at their maximum levels, and some of the older pesticides have been replaced by cheaper and/or more effective pesticides. For example, Carlson points out that linuron, an older pesticide, is approved for use on wheat, corn, and other crops, but surveys indicate little use except for soybeans. The Archibald and Winter study assumed residue levels were equal to actual residue levels found in FDA surveys of supermarket foods.

cause of lack of tests to obtain the potency factors (toxicity) for the remaining twenty-five compounds. While these twenty-eight compounds comprise some of the most widely used pesticides, toxicity data on the remaining twenty-five compounds are necessary to conduct a complete analysis.

Improved models of toxicity also are needed (Finkel, Ames and Gold). Toxicity is extrapolated from animal feeding studies in which sensitive rodent species are fed large doses of the chemical. The dose-response relationship is usually assumed to be linear throughout the entire dosage spectrum. In some cases, multistage dose response models are used. These models extend the simple linear model to include a series of two or more linear segments. When extrapolating from rodents to humans, adjustments are made for lifespan, bodyweight, and species sensitivity. Data needs include improved dose-response models, information on the health effects of metabolites of chemicals as well as the chemical itself, and an expanded scope of health outcomes to include not only tumors but also neurological effects, effects on fetuses, effects on the functioning of the immune system, and other adverse health effects.

Improved data on levels of microbial or chemical hazards in foods and whether these levels are a risk to human health are essential for designing effective control programs. Identifying which foods contain contaminants are suggestive, but the link to human illness is crucial because of variability in the dose needed to cause illness and impact of food preparation and handling methods which often dramatically reduce contamination levels (or in the case of bacteria, can also increase contamination levels by cross-contaminating clean foods or bacterial multiplication).

More data are needed to identify populations particularly vulnerable to foodborne illness and identify their likely disease severities. Some people may be more vulnerable either because of diet or individual characteristics. Depending on the microbial pathogen, such groups can include infants, persons taking antacids or antibiotics, persons who are genetically low acid secretors, persons with new organ transplants or on chemotherapy, diabetics, alcoholics, AIDS patients, and the elderly with no underlying disease. For chemical contaminants, the young are particularly vulnerable because of their long life expectancy, higher metabolism, and perhaps greater intake per unit of body weight. Identifying

groups susceptible to foodborne disease requires the linkage of usual food intake patterns with actual contamination levels.³

Funding for the collection of new data is essential for developing a statistical framework for estimating which foods are vehicles for various chemical or microbial contaminants causing human illness. For chemicals, the new USDA data initiative is collecting much of this data (see below). For microbial risks, data needed include:

(a) Increased funding for CDC investigations of foodborne disease outbreaks to include, routinely, the replication of likely food-handling procedures which could have caused the outbreak. This exercise would improve the identification of the causative organisms (currently 60% are never identified) and would yield more specific information on what conditions are likely and unlikely to lead to foodborne disease outbreaks for specific pathogens—information crucial for setting up HACCP (Hazard Analysis at Critical Control Points) systems.

(b) Funding to assist states, counties, and cities in identifying and investigating foodborne disease outbreaks and perhaps funding for CDC to set up new data collection systems from states.

(c) Funding of additional case/control studies to determine the etiological fraction, e.g., identify what foods are associated with which foodborne pathogens. While these studies are expensive,⁴ they may be the most cost-effective method of building a statistically valid data base for newly identified foodborne pathogens and developing a consensus among public health professionals, industry, and regulators as to the relative importance of various foods as vehicles for specific microbial foodborne diseases.

Identification of the entry point where hazards enter the food chain is also missing data. Once the foods containing contaminants posing human health risks have been identified, the point of entry into the food chain needs to be identified. Because microbial and chemical contaminants can enter the food chain at any point from the

³ The NAS study of pesticides assumed that food consumption was at the 95% confidence limit for food weight for each of 273 food forms in the 1977–78 USDA Nationwide Food Consumption Survey. While this may understate exposure for certain individuals, it overstates average exposure and does not account for substitutions in consumption that are likely to occur. For example, an individual consuming large quantities of one item is likely to consume less of another during a particular day. In other words, the distribution of usual intake is likely to show less variation than that observed in a one-day intake survey and hence have a lower 95% confidence limit.

⁴ The Seattle-King County study identifying chicken as the greatest source of campylobacteriosis risk cost FDA \$800,000.

farm to the point of consumption, control options exist at all these points. This would involve sampling at all levels of the production and marketing system to develop a statistically valid data base for both microbial and chemical risks. Sampling should start with the foodborne disease hazards causing the highest social costs and those that can be easily controlled.

Production function tradeoffs affecting microbial and chemical contamination of foods are needed for farm production, processing, and food-handling practices. Some of the production function data are known, but much remains unknown. For chemical hazards, basic data are needed on types and amounts of chemicals used on specific crops by geographic regions, crop yields and quality at alternative chemical usage levels, alternative input substitutions, and cropping patterns. For example, what are the effects of integrated pest management on specific crop yields and quality in specific geographic regions, under specific weather conditions, and what is the impact on agricultural chemical usage levels and residues in foods.

For microbial hazards, data are needed identifying likely microbial contamination levels with various farm management procedures, processing procedures, transportation practices, and food handling procedures (Wenger et al.). For instance, some scientists believe that *Salmonella* and *Campylobacter* can be controlled or eliminated in poultry flocks by control of eggs, feed, and environmental conditions (such as chlorinating drinking water). Economic data are needed for evaluation of these alternatives.

Economic and Behavioral Science Data Needs

Private and public risk management strategies require that the economic and other behavioral factors that affect decisions of suppliers, consumers, and regulators be taken into account (table 3). Options for control programs need to be evaluated to determine the combination that maximizes social welfare. The National Academy of Sciences has concluded that the current meat and poultry inspection system based on visual inspection cannot detect the most important microbial risks (1985, 1987, 1990a,b). The changing scientific ability to rapidly test for microbial pathogens creates an opportunity to revamp regulatory approaches. For example, FSIS is using recent advances in rapid detection methods for a *Listeria* control program.

Table 3. Economic Data Needs

<u>Economic Assessment of Risks</u>
Identification of hazard
Toxicity/microbial virulence
Exposure
Costs: consumers, industry, public
<u>Demand Issues</u>
Demand for and value of information
Risk perception
Demand for product attributes (appearance/taste/safety tradeoffs)
Willingness to pay/contingent evaluation
Consumption and exposure
Consumer demand and intercommodity relationships
<u>Private Strategies and Supply Issues</u>

Costs and benefits of risk control/management strategies
Vertical market integration/contract specification for inputs
Industry self-regulation
Third-party certification/labelling/branding
Cost of production
<u>Market Interrelationships and Government Intervention</u>
Supply/demand
Farm program and input (agrichemical) usage
Marketing orders/grades and standards/agrichemical usage
Inspection/labelling/standards for microbial and chemical residues
Environmental effects
Federal/state/foreign jurisdiction
Tracking systems for feed, food, and chemicals

(a) Estimate the benefits and costs of farm management strategies to prevent farm-level microbial and chemical contaminants. Basic economic data are needed to estimate the possible cost increases associated with farm management strategies identified in the physical/biological data needs section. One such farm-level analysis would be estimating costs of eliminating parasites, such as *Taxoplasma gondii* and *Trichinella spiralis*, on hog farms. New data from the National Animal Health Monitoring System may be helpful in answering questions about the effectiveness and cost of alternative farm management strategies for reducing microbial contamination of food animals. In estimating the human illness prevention benefits of farm control, it is advisable to estimate both the cost of illness avoided as well as the willingness to pay for safer meat and poultry products. (The cost-of-illness measure is more easily understood by the public and members of Congress, while the willingness-to-pay measures are more comprehensive but are still in the developmental stage of public acceptability.)

(b) Predict/understand how farmers choose alternative production practices. What price differential between pesticides will trigger a switch to another chemical or cause a switch to organic production? How do farmers obtain information about farm chemical risks, prices, and effects on pests? What are the resource requirements and substitutions in terms of management skills, labor, capital, and variable inputs (and their related costs, productivity, and production risks) for alternative farm production systems? How do farmers evaluate their own risks to pesticide application exposure, environmental damage, and ground water contamination and how does this knowledge affect behavior?

(c) Identify the benefits and costs of control strategies beyond the farm gate. For parasites, thorough cooking or irradiation are the only options for reduction of human exposure because parasites do not multiply in the meat and are hardy survivors during traditional food handling, processing, and transporting. For most bacteria, there are other possibilities, because cross-contamination and multiplication are likely during food processing, handling, and transporting. Another class of organisms are bacteria-producing, heat-stable toxins which cannot be eliminated by thorough cooking; here the keys are either preventing bacterial contamination or preventing toxin production during processing, handling, and transporting.

For chemicals, we need to understand processors' choices of fumigants, food additives, and other chemicals. Data on producer and marketer strategies to manage food safety need to be collected to evaluate the efficiency and viability of private market alternatives to government regulation. Recent evidence suggests that food safety is becoming an important marketing strategy for food retailers. Kaufman and Newton note that the use of third-party residue testing and certification services for fresh fruits and vegetables grew from a single supermarket chain in 1987 to 14 retailers in 1989 operating more than 740 grocery stores. Despite its growing importance, little data are available on the costs, prevalence, and types of products included, specific tests or assurance methods, labelling, availability of organic produce, and related market assurance activities. To what extent do marketers enter into forward contracts with farmers that include specifications on pesticide usage and residues? Would marketing grades specifying food safety attributes improve market efficiency?

(d) Study consumer behavior to determine ex-

posure and consumers' food safety preferences. Consumers, to varying degrees, have some control over foodborne disease risk. For example, they can wash produce, peel skins, and remove outer leaves where pesticide residues and microbes tend to concentrate; purchase a variety of foods; avoid more risky foods; buy organic produce or "certified residue free;" cook meat, poultry, and seafood thoroughly; refrigerate cooked foods promptly and keep refrigeration temperatures around 35 degrees Fahrenheit; and practice improved kitchen sanitation. Food safety policies can also affect the prices, qualities, and availability of foods. Thus, there is a need for this basic demand data to evaluate market impacts and consumer welfare.

Data are needed to conduct research on underlying consumer behavior issues, such as consumer demand for alternative product attributes, e.g., flavor, appearance, pesticide residues, and product price, willingness to pay for safer foods, demand for organic and pesticide-free produce. Very little data are currently available to research these issues. This would necessitate the collection of data at the household or individual level. Questions on consume risk perception, awareness, and attitudes also need to be included in survey instruments. If a link between cosmetic appearance and pesticide residues is shown to exist, how willing are consumers to make tradeoffs between cosmetic appearance and pesticide residues? These research issues will require new surveys of consumers with new survey instruments. Conjoint analysis and contingent market evaluation techniques will be necessary to elicit some of the underlying aspects of behavior.

The Alar controversy indicated increased public concern about particularly vulnerable groups. It also suggested that designing different regulatory programs for different segments of the population may optimize social welfare. Special regulatory interventions may be desired for some of these groups, such as special labels on meat and poultry identifying product risks, special labels with handling and cooking instructions, certification programs for products with reduced pathogen levels. (FDA has been targeting AIDS patients with special food handling advice [ref]). Focus group work would be necessary to evaluate how these programs might be valued and received by consumers.

(e) Once technically feasible strategies have been identified, economical and socially optimal regulatory programs and enforcement strategies need to be identified and evaluated. Ac-

tions such as slaughterhouse tests, farm level inspections, fines for contaminated carcasses, or required cooking for carcasses from farms with contaminated animals are some of the regulatory options available for controlling contamination of raw meat and poultry. How each strategy can be expected to alter farm management practices should be modeled and the benefits and costs of each alternative compared. Strategies at later points in processing, handling, and transporting also need to be evaluated. One such study could compare the legal tools, enforcement, and effectiveness of federal programs and policies.

Regulators need better data to trace agricultural products through the marketing system. This information would allow for improved crisis management of foodborne hazards, improved enforcement activities, and provide a mechanism for shifting product liability back to the responsible party.

The USDA Food Safety Data Initiative

The USDA food safety data initiative is a closely coordinated effort of four agencies to gather data on agricultural chemicals in the food system (table 4). For the USDA effort, the National Agricultural Statistics Service (NASS) is collecting data on pesticide use at the farm level, the Agricultural Marketing Service (AMS) is collecting pesticide residue data on fresh fruits and vegetables, the Human Nutrition Information Service (HNIS) is developing exposure models based on its surveys of food intake of individuals, and the Economic Research Service (ERS) is analyzing the economic implication of alternative means of reducing residue levels. The USDA initiative is being coordinated with FDA and EPA, the two other federal agencies with responsibility for regulating pesticides in the food supply.

The National Agricultural Statistics Service

will be responsible for collecting pesticide usage levels and practices. The data will allow for the identification of usage levels for specific chemicals by crop and geographic region. Economic data on farm resources, production practices, and input prices also will be collected. During the first year of the initiative, data collection efforts will focus on chemical usage on domestically produced fresh marketed vegetables in the five major vegetable-producing states. Efforts during the second year will focus on fresh fruits and nuts.

The Agricultural Marketing Service, working with individual states, will be responsible for collecting statistically based data for pesticide residues in selected fresh fruits and vegetables grown in the United States. The data will be used to improve the quality and quantity of information on actual pesticide residues for regulatory purposes as well as to inform and assure the public on actual pesticide residue levels. AMS is working closely with EPA in prioritizing chemicals for residue testing and deciding upon appropriate laboratory procedures. AMS will provide funds and other resources to participating states to adapt their programs to a standardized system for sample collection, analysis, and reportage.

The Human Nutrition Information Service will develop a residue exposure assessment system. HNIS survey data on individual intake will be linked to residue data obtained from AMS data collection efforts. By linking HNIS survey data on individual intake to residue data from AMS data collection efforts, the system will provide data on the potential exposure of individuals to pesticide residues found on agricultural products. In addition, data on the amounts of more than 5 000 different food items will be translated back to the agricultural products of which they are comprised via recipes for linkage to the farm pesticide usage data.

Discussion

The efficient control and management of food safety risks requires the synthesis of data and information from a number of physical, biological, and behavioral sciences. The process of information synthesis is technologically complex and fraught with uncertainty. The uncertainty arises from three major sources: limited science, limited technology, and limited data. One should not expect new data to completely eliminate uncertainty from the food safety risk assessment

Table 4. USDA's Food Safety Initiative

1. Identifies the set of residues to be monitored and their toxicity.
2. Identifies entry point into the food system and surveillance point.
3. Develops sampling requirements, procedures, alternatives, analytical methods of detection, and cost.
4. Measures exposure.
5. Coordinates data-gathering efforts.
6. Collects related economic data affecting the decision-making behavior of market participants: producers, consumers, and regulators (see table 3).

and management problem because of diminishing returns and increasing marginal costs. There is a tradeoff in resource allocation, and one must choose wisely among those activities designed to reduce uncertainty and improve decision making such as the collection of new data. A number of important factors are identified in this paper that provide insight into the factors that influence food safety decisions and the degree of uncertainty regarding their impact. This information, together with costs of obtaining data to improve our knowledge, will guide us in the selection of new food safety data collection efforts.

A science-based approach to food safety issues is data intensive. Data are needed for risk assessment, identification of points of entry into the food chain, tracking substances as they move through the food system, analyzing the behavior and perceptions of market participants, communicating disparities between real and perceived risks, and measuring the costs and benefits of alternative control options. For example, the National Academy of Sciences in 1969 identified steps that could be taken to prevent *Salmonella* contamination of raw meat and poultry. These procedures have not been implemented, and human illness of salmonellosis have increased in the United States. Economic studies of the costs and benefits of alternative farm management practices are needed before industry and regulators will be willing to make decisions about adopting new practices.

In addition, the changing nature of scientific knowledge in the food safety area means that new possibilities for assessing and controlling food safety risks are emerging. Federal funding of basic research to speed up the emergence of scientific knowledge is a standard economic textbooks' example of a public good. With a public good, the private sector cannot capture the full return to society of the new scientific knowledge; once the invention has occurred, anyone can use the knowledge regardless of whether or not they pay for it.

Current estimates of foodborne disease risk suggest that microbial and other natural toxic components are the greatest sources of risk. Current progress on identifying microbial risks and sources in food is pointing the way to control options. However, additional data are needed to conduct benefit/cost analyses of alternative control options and will require interdisciplinary cooperation to combine the underlying physical and technical relationships together with the economic and behavioral aspects of market par-

ticipants. In conclusion, optimal public and private strategies to assess and manage food safety issues require that additional data be collected, analyzed, and integrated into public and private decision making. The greatest social welfare gains are likely to be garnered by collecting data on microbial hazards and control options—the source of the greatest human health risk and a compliment to USDA's data initiative on chemicals.

Data Needs to Assess Environmental Quality Issues Related to Agricultural and Rural Areas: Discussion

David E. Ervin

Environmental quality issues are now prominent in virtually all comprehensive agricultural and rural policy discussions. The demand for data to analyze these issues, therefore, is strong, reflecting public concern about agriculture's diverse impacts on the environment. Moreover, the current era's environmental issues require new temporal and spatial data because of the prominent roles of uncertainty (e.g., groundwater quality, food safety) and broader geographic coverage (e.g., global change). It is within this context of volatile policy discussions and uncertain science that critical data choices must be made.

Fletcher and Phipps (FP) provide a comprehensive survey of the wide variety of data management issues related to agriculture-environment topics. They do a good job at covering a broad array of questions that are crucial to the construction of a high quality database to support sound science and policy development. In this brief discussion, I will emphasize five points that are consistent with the FP paper and that are especially relevant to aggregate policy analysis.

Monitoring and research questions should drive data collection. The authors make this point, but it merits further emphasis. I am using monitoring in the broadest sense here to include the potential pollutant loadings, environmental performance variables, and demand characteristics for environmental services. While there will always be discussion as to which are the relevant questions in science and policy circles, the

"right" data cannot be collected without first asking the "right" questions. To that end, I would have preferred that FP attempt to specify some of what they feel are the dominant questions regarding agriculture and environmental quality. An example from the Just and Antle analysis is, to what extent a farmer input behavior is causally related to by natural resource-environmental characteristics.

Different levels of resolution are needed for general monitoring and for analytical research. Monitoring information can be very useful in defining relevant research questions, and research findings may identify missing environmental monitoring indicators. While these interrelationships exist, an agriculture-environmental quality database strategy should recognize that the two activities often require different types of data. For example, national and state agricultural chemical use data can be helpful for targeting research efforts to those geographic areas and/or production systems more likely to experience environmental problems.

Existing data and science are inadequate to provide the theoretical framework and sampling procedures to understand aggregate agriculture-environment interactions. Thus, aggregate data management involves many choices under very uncertain conditions. A good example of this point is an exercise recently attempted under the president's Water Quality Initiative in agriculture. The objective was to devise a matrix of major agricultural activities and groundwater vulnerability conditions to sample geographic areas. Not only were data unavailable to assign cell probabilities, but the cooperating physical scientists indicated that an acceptable vulnerability measure is not at hand. However,

David E. Ervin is chief, Resource Policy Branch, Resources and Technology Division, Economic Research Service, U.S. Department of Agriculture.

The comments and views expressed in this article are the author's and not necessarily those of the U.S. Department of Agriculture.

by asking a policy-relevant question, future data collection can be designed to reduce that uncertainty and improve scientific understanding. How do we answer aggregate water quality economics questions in the meantime? Perhaps the best approach is to use smaller area study knowledge to parameterize input-input, input-output, and output-output relationships in aggregate regional/national simulation models and then use the price-quantity endogenous aggregate results to analyze economic and environmental adjustments in what are considered the "major" agriculture-water quality cases.

Emphasize the understanding of economic behavior related to natural resource/environmental conditions. Just and Antle have presented a very appealing conceptual framework with which to analyze agriculture-environmental quality interactions. Their emphasis is on the joint spatial and temporal distributions of physical and economic data for analyzing the effects of alternative policies. Underlying their discussion is the fundamental point that we must understand economic behavioral processes in relation to the environment to predict the consequences of those policies. With the appearance of a plethora of intriguing environmental process simulation models, there is a distinct risk of economists not allocating enough effort to the economic behavioral questions. Clearly, our comparative advantage is applied economic, but incorporating environmental process detail is needed to un-

derstand behavior. The data design implications are straightforward.

Geographic information systems technology holds considerable promise for overview monitoring, but its analytical research potential is unclear. As FP indicate, GIS is a powerful emerging technology. Its strength lies in organizing different and sometimes disparate data sets to portray spatial economic and environmental relationships. The best level of resolution for GIS use is still unclear, i.e., small area studies or aggregate overviews. The answer is probably not uniform but depends upon the economic and environmental processes under analysis. If close detail is necessary to understand variation in significant economic and environmental patterns (e.g., input use and ag chemical leaching), then small area GIS applications are warranted. In contrast, if those relationships are fairly constant over large spatial units, then aggregate summarization is possible. What is not at all clear is whether GIS technology can be effectively used in behavioral analytic exercises. To date, such analyses are not forthcoming. Perhaps we are just in the early stages of technology adoption.

Data Needs to Address Economic Issues in Food Safety: Discussion

Julie A. Caswell

What are the economically significant food safety risks facing the U.S. population? What are the most cost-effective means of controlling (managing) these risks? These are straightforward questions; yet, as the paper by Roberts and Smallwood indicates, the answers require a complex array of information only parts of which are currently available. Discussion of data needs necessarily generates a list. But what makes for a good list, as opposed to a laundry list?

Roberts and Smallwood organize their list by dividing food safety data needs into two broad categories: physical/biological and economic/behavioral. They also consistently distinguish between food-related risk from microbial and chemical sources. The latter includes possible risks associated with pesticides, animal drugs, environmental contaminants, and additives. In the physical/biological area, their list of data needs includes risk assessment information for risks from both microbial and chemical sources in food products, information on levels of contaminants, risks to human health, entry points, and production function tradeoffs. These correspond roughly to the first three steps of the National Academy of Sciences' (NAS) four-step risk assessment procedure: hazard identification, dose-response assessment, and exposure assessment. The economic/behavioral category of data needs corresponds to the fourth step in the NAS's process: risk characterization. It is helpful, I think, to locate individual data needs in the context of this existing NAS framework and to piggyback off prior efforts. The Roberts and Smallwood paper provides a very serviceable list of data needs from which to carry forward this process.

Economists are ultimately end users of the array of physical/biological data needed for analysis of food safety issues. Their major task in this area is to work with researchers from other disciplines to insure that data collection systems are designed to generate information in formats

amenable to economic analysis. Because these data sets are destined to be put to multiple analytical purposes, quality of design is critical. An example of this involvement in survey design is contained in recent work by Carriquiry, Jensen, and Nusser. They suggest design features for the USDA Nationwide Food Consumption Survey to insure that statistically sound measures of distributions of usual daily exposures for individuals can be generated. This type of work is very important to the availability of useful data sets for the 1990s and beyond.

In the economic/behavioral category of data needs, economists should, of course, be providing leadership in data collection efforts. The table of categorical data needs in this area developed by Roberts and Smallwood is particularly helpful in emphasizing the set of private (consumer, firm) strategies and public (government) policies that affect the benefits and costs, and the distribution of benefits and costs, associated with management of food safety risks. Of great interest here are recent shifts in firms' incentives to produce, label, and advertise "safe" products as a result of increased consumer demand for safety attributes in food products (see e.g., Ippolito and Mathios). This new market-based incentive structure will interact with the federal government's regulatory system in ways that promise to be difficult to evaluate from a social benefit/cost perspective.

In the end, economists play an integrative role bringing together the physical/biological and economic/behavioral data to answer the questions I began with: What are the economically significant food safety risks and what are the most cost-effective means of managing them? An excellent road map to this type of effort can be found in recent work by Curtin and Krystynak on salmonella control in Canada. This work integrates data on the incidence of salmonella contamination at different stages in the processing and distribution of poultry products with estimates of the benefits and costs of control strategies at those stages.

An important issue not addressed by the Rob-

Julie A. Caswell is an associate professor, Department of Resource Economics, University of Massachusetts at Amherst.

erts and Smallwood paper is the relationship between the data needed for the management of microbial and chemical food safety risks and that needed for management of nutrition- and diet-related food risks (e.g., heart disease, colon cancer). Yet, within the hierarchy of the federal government's regulatory agenda, all food-related risks will, at least implicitly, be considered as a group and resources will be allocated within this grouping. Fortunately, many data bases, such as the USDA Nationwide Food Consumption Survey, provide information useful for calculating exposure to multiple risks. Elsewhere, however, data needs are not overlapping, and choices about where to commit resources must be made.

What are the priorities among the food-safety-related data needs on Roberts and Smallwood's list? How do politics and public perceptions affect the extent to which these data needs are being addressed? As economists have come to know, and in part respect, there are differences in the food safety priorities of consumers, consumer advocates, processors, retailers, government regulators, and "scientists." If, as Roberts and Smallwood argue, and I agree, social welfare gains will be realized by developing improved food safety information, then the priority-setting

process will be key to the timing and size of these gains. Now that we have the makings of a good list of data needs, our attention should shift to mapping where to start, making maximum use of available data and developing new data sources such as the USDA Food Safety Data Initiative. It is also important, while drawing this map of the food safety neighborhood, to remember that there is a bigger world of consumer risks out there and that the larger scale tradeoffs between management of different classes of risk is the ultimate economic issue.

The Role of Aid and Capital Flows in Economic Development

Uma Lele and Ijaz Nabi

Prior to the debt crisis which commenced in 1982 when Mexico defaulted on its debt repayments, annual capital flows to developing countries amounted to \$100 billion and official concessional aid flows consisted of an additional \$50 billion. After the debt crisis, commercial flows dried up almost completely with net transfers of capital from borrowing countries to their lenders. The concessional flows which had grown dramatically in the 1970s also stagnated in real terms. Over the four post-World War II decades, billions of dollars have been transferred from developed to developing countries. During this period there have been major structural changes in the patterns of external assistance including the graduation of a number of recipients, such as Greece, Taiwan, and South Korea, the decline of the U.S. role as a donor, the rise of Europe and Japan in external assistance, and a shift of aid resources from Asia to Africa. Whether these transfers have succeeded in stimulating growth, reducing poverty, and creating human and institutional capacity to carry out the development effort is a matter of considerable controversy. Econometric studies that have attempted to establish the effect of capital flows on savings, investment, or growth have turned out to show little relationship.

The authors of this paper assembled a group of scholars from developed and developing countries with hands-on experience in development policy to explore the role of external capital in economic development around a well-defined comparative framework. Eleven country case studies on Asian, Latin American, and

African countries¹ were undertaken by these scholars together with four cross-country, issues-oriented studies on bilateral and multilateral aid, food aid, on the process of transition from concessional to commercial capital flows, and on some of the latest instruments of capital transfers. Even while being a small fraction, external finance can make an important contribution to the development process by transferring technology and information, creating institutions, developing human capital, and increasing the supply of critical public goods the shortage of which hamstrings development at early stages. The study addressed the extent to which, and the conditions under which, these potentially positive effects of aid were realized and the factors explaining them.

The overall results of the study are presented first in the form of general lessons for recipients, official donors, and lenders. These are followed by country-specified highlights from which the general conclusions are derived.

A large amount of external capital has not been the most important factor in economic development. Country policies made the most difference. In countries with sound economic policies, a limited amount of well-conceived external assistance helped improve the capacity of the recipient countries to plan and implement overall policies and programs as well as to develop the critical physical and social infrastructure needed to accelerate growth. Even large amounts of external capital could not effectively substitute for unsound internal economic management (i.e., a public investment program not geared to the broad-based provision of physical and human capital, large fiscal deficits, high inflation rates, and low internal mobilization of capital). Outward-oriented development policies involving relatively few distortions and restrictions in

The authors are, respectively, Graduate Research Professor of International Economic Development at the University of Florida, and a senior economist at the World Bank.

This paper is based on the findings of a cross-country study of aid and development coordinated and edited by the authors and published in a book, *Transitions in Development: The Role of Aid and Commercial Flows*. San Francisco: ICS Press, Apr. 1991.

¹ Countries include India, Pakistan, Sri Lanka, Thailand, Egypt, Mexico, Brazil, Columbia, Kenya, Tanzania, and Senegal.

the economy were more conducive to rapid growth compared to inward-oriented policies. When accompanied by a broad-based public investment program in support of education, health, and other social sectors, outward-oriented policies also achieved more equity than inward-oriented policies as they achieve rapid growth in employment. Because removal of distortions through policy reforms is a painful process challenging many vested interests, external capital was able to provide an important cushion to soften the adjustment process until the economies could respond to the reforms. The lack of access to external finance on a long-term assured basis often terminated the reform process which was underway.

Countries that succeeded in achieving a broad-based development of their agricultural sectors achieved more efficient growth than those that neglected their agriculture. Given that agriculture contained the bulk of the population, broad-based agricultural growth played an important role in generating employment and reducing the proportion of the population living in poverty. In several cases, especially in Asia, external financial and technical assistance played an important role in fueling agricultural growth through investment in human capital, institutions, and technological change. Food aid, too, played an important role in Asia in ensuring an adequate amount of food to the poor and vulnerable groups when countries could ill afford to import food. Moreover, food aid provided the crucial foreign exchange needed by countries at early stages of development and frequently facing a balance-of-payments crunch because laying foundations of broad-based agricultural development involved substantial gestation lags before acceleration in the growth of agriculture could occur. Food aid did not play such a positive long-run role in generating agricultural growth in Africa, where internal price and other policy distortions turned out to be insurmountable, although it increased the food supply in the short run.

Another key to broad-based growth was the investment in human capital. Access to universal primary and secondary education, health care, and water were essential to promote broad-based participation of the poor in the growth process. While external aid can play an important role in such investments which tend to face long gestation lags in producing returns, aid did not always play this role. Not only the governments, but even the givers of large aid, neglected the importance of human capital.

Whereas the content of domestic policies explain part of the puzzle of who succeeded in development, the type of aid given also made a big difference to its productivity. Far too much of the aid was given for strategic, commercial, or short-term political reasons and too little for long-term economic development. Aid given for political reasons also tended to be highly unstable. Large fluctuations in the amounts of external capital made it impossible for the recipients to plan uses of aid for long-term investments, e.g., in social expenditures with long gestation lags. Contrary to the permanent income hypothesis, which expects actors to save much of the windfall in income, recipients used the "aid boom" in much the same way as they did commodity booms. They squandered it on unproductive expenditures including growth of governments. The results of the study suggest clearly that, if development is the objective, aid should be given to countries with conducive economic policies, although humanitarian aid may be given to the least developed countries with large concentrations of the poor. Donors also need to avoid fads which make them shift aid allocations from one type of project to another and between project and program aid, although the underlying reasons are well founded for the apparent fashions in aid, e.g., the concern about poverty in the 1970s, macropolicy reform in the first half of the 1980s, and the environment in the second half of the 1980s. The challenge for aid donors has been to address these multidimensional aspects of development successfully.

Aid tying by bilateral donors has been another problem. It has led to transfer of inappropriate technology and economically unjustified projects, leading to suboptimal use of both aid and national funds.

As countries become more economically advanced, they tend to rely less on official aid and increasingly on private sources of capital. Commercial borrowing offers many advantages, but only when it is demanded in moderate quantities; it does not replace internally mobilized resources, and it can be adequately serviced, for example when external terms of trade are favorable. However, the transition from concessional to commercial capital flows is neither smooth nor unidirectional.

Massive amounts of private capital were loaned to developing countries by banks in the 1970s without regard to, or knowledge about, the conditions in which the capital was being deployed or the conditions under which it could be repaid.

Private capital was often used no more productively than public capital, especially politically and commercially driven bilateral aid. It resulted in prestigious megaprojects yielding low returns and an overstretched public sector. Fluctuations in external terms of trade compounded the debt-servicing problem of developing countries saddled with poor investment portfolios. Unless commercial banks invest in developing a better understanding of borrower circumstances and recognize the implications of volatility in external terms of trade for debt repayment, private capital will continue to be poorly allocated. Consequently it will be both unpredictable and unproductive.

In situations of unfavorable policy regimes characterized by serious distortions, external aid and private capital actually proved harmful to countries. By providing massive amounts of capital, donors and lenders contributed to the Dutch Disease by expanding the nontraded public goods sector, exacerbating distortions, and strengthening vested interests. It is clear that commercial banks must share in the burden of this past massive misallocation of capital by sharing in the debt burden of developing countries. Without a major reduction in the debt, it is unlikely that investment in the highly indebted developing countries will resume. On the contrary, those countries who had already made a transition from concessional to commercial capital have had to resort to official assistance to maintain some flow of capital and to reduce the net outward transfers made necessary by heavy debt servicing.

Country performance varied greatly among those selected for analysis. India, one of the poorest countries, received the most concessional assistance in total, although it was minuscule in per capita terms because of its large population. India is a relatively successful case of aid's role in development, especially in the development of its agriculture which led to acceleration in food production and some major reduction in poverty. India needs more concessional aid for investment in the social and physical infrastructure to alleviate its massive poverty. Growth performance of Pakistan, also one of the poorest countries at independence was better than India's, although its social indicators—especially with regard to women—remained some of the lowest. Pakistan experienced major fluctuations in aid because of its strategic geopolitical situation. Wars in Vietnam and Afghanistan determined aid levels. Trade

liberalization in Pakistan was associated with periods of large aid flows and arrested when aid dried up. Egypt, too, received massive aid flows for geopolitical reasons with sources of aid shifting constantly between the Eastern and the Western blocs. Aid contributed to the Dutch Disease. Egypt's economic performance was not commensurate with the levels of aid given to it. Sri Lanka, too, received massive aid and, as in the case of Egypt, sources of aid changed. Eastern bloc countries dominated in aid flows when socialists were in power, and the West dominated when the more market-oriented political party was in power. Aid had little direct influence on Sri Lanka's economic policies however, although socialist governments fared poorly relative to the market-oriented ones, not only in achieving growth but also in fostering equity.

Thailand is one of the most successful cases of rapid growth and broad-based development. The government of Thailand focused on a balanced program of public investment designed to increase the supply of public goods and pursued macroeconomic management that offered an enabling environment for the private sector with a relatively minor role of the government in directly productive activities. Thailand's biggest challenge is to increase internal resource mobilization and maintain its debt servicing under control.

Among the three Latin countries, only Colombia pursued stable and conservative macroeconomic policies, and it was a steady performer. Nevertheless Colombia has encountered difficulties in access to external capital due to the "Latin Syndrome" of private banks. Mexico had a relatively well-managed economy until the 1970s, but the country went on a binge in borrowing at the tail end of the decade and got into macroeconomic difficulties. Mexico has undertaken one of the most ambitious programs of structural adjustment since 1988 and has resumed some access to external capital. Whether this is enough to achieve sustained and broad-based growth remains to be seen. Brazil's miracle was based on an import substitution policy. External capital Brazil borrowed in the 1970s was largely misallocated, and internal reforms have been slower in coming.

Only Kenya performed well among the three African countries selected for analysis. Tanzania and Senegal were large recipients of aid. Their acute import substitution policies were reinforced by external aid, which caused rapid growth of government and reinforced the decline in per

capita incomes caused in part by adverse external terms of trade, and by poor internal economic policies.

The examples of these countries show that external capital is not always a blessing, and too

much of it can be a particularly bad thing. On the other hand, there are several examples in which a small amount of external capital has played an important catalytic role in accelerating economic growth and alleviating poverty.

Investments to Transfer Poultry Production to Developing Countries

Gary Vocke

World chicken meat production is steadily increasing (fig. 1). Much of this meat is produced in controlled environment, confinement systems that break agriculture's traditional ties to land and climate. This break makes confinement poultry production transferable to almost anywhere in the world, including developing countries. Thus, in developing countries the technology employed in confinement poultry is often more advanced than in other sectors of agriculture.

After an introductory overview, investment options for modern broiler production and processing in developing countries are outlined. A brief history of the spread of broiler production shows the transferability of the underlying technology. The paper concludes with data about the increasing dependency of many developing countries on imported feedstuffs to supply their expanding livestock industries.

Technology and Income Transform Agriculture

The transition of developing countries from food grain-based agriculture to include feed production and confinement raising of poultry and other livestock is a major long-term trend with rising incomes and urbanization. As incomes rise, people change their diet, usually including more livestock products. Not only does home consumption rise, with urbanization more products are marketed through fast-food shops, for which poultry products are well suited. Further, people are usually willing to pay more for fresh meat than frozen, imported meat. Thus, when personal incomes rise and the number of urban consumers is large enough to create a viable market, the technology for confinement poultry production readily transfers from developed countries for local production of chickens.

Gary Vocke is an economist with the Economic Research Service, U.S. Department of Agriculture.

Spread of Modern Poultry Production Requires Investment

Krostitz estimated in 1988 that in the higher-income countries of Latin America, North Africa, and the Far East, the proportion of chicken production in modern systems is between 70% and 90% of total output. In Middle Eastern OPEC countries, it is above 90%. Even in many of the lower-income countries in Asia and Africa, the proportion of the total output coming from modern operations is between one- and two-thirds. Krostitz also estimated that the investments for developing country poultry operations are about U.S. \$30 billion at today's prices.

The firm-level investments discussed here for a modern broiler operation in developing countries rely on a World Bank study of integrated broiler production. The minimum size considered by the World Bank produces 2.5 million broilers annually. Although 2.5 million is large, a Michigan State University study prepared at the same time assumed the minimum U.S. size to be 15 million broilers annually (Lasley).

Buildings for the various operations can be constructed using local materials and labor, so investment costs will vary by country. Most of the equipment, however, will likely be imported from international suppliers (see table 1).

In addition to the investments shown in table 1, large storage facilities will be needed where timely grain deliveries are uncertain. Further, if grains are purchased locally, drying equipment will be needed. If temperatures go over 95–100 degrees Fahrenheit frequently, the breeder and growout houses will need equipment to cool the air.

Another investment decision is the extent to automate. On average, one person using hand feeders and waterers can raise 7,000 broilers at a time. Automated feeding and watering increases the number of broilers per worker to 20,000, but raises equipment investment 280%. For comparison, fully automated U.S. facilities allow one person to raise 80,000 broilers at a time with only a half day of work. Automated

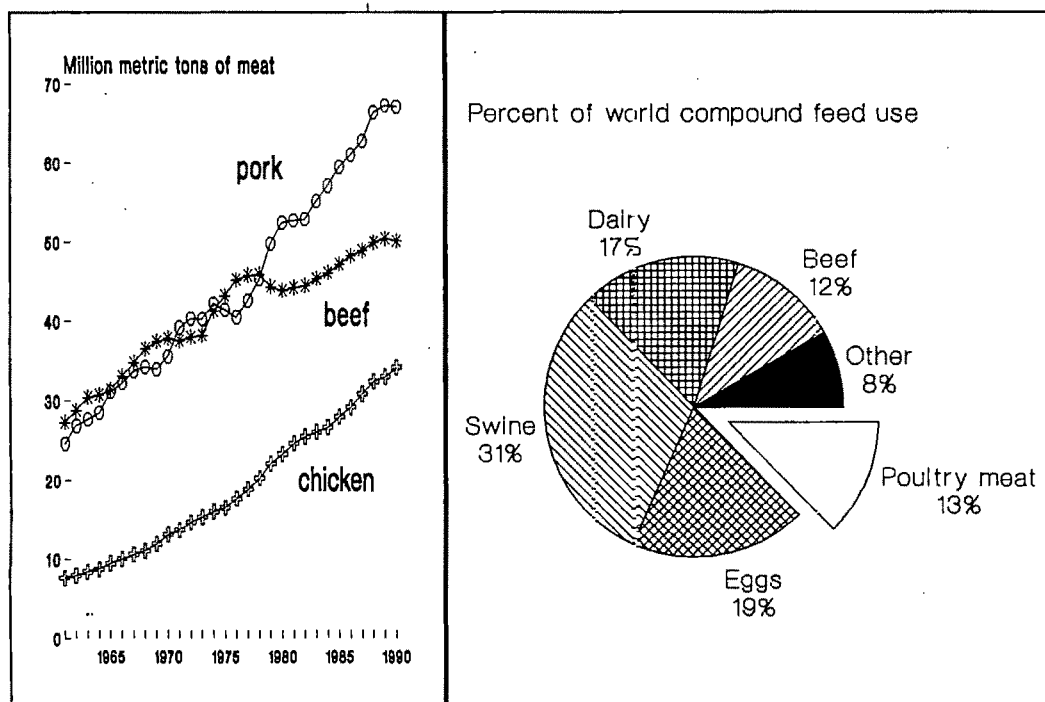

Figure 1. With present trends, poultry and swine will be increasing their share of world meat output and feed use (FAO, Vocke)

watering and feeding in breeder houses raises equipment investment 330%, but increases the number of layers per worker from 2,000 to only 2,500. There is less labor savings with breeder hens because most of the labor is for collecting the hatching eggs.

Facilities for feed milling, incubation of hatching eggs, and broiler processing require relatively large equipment investments and provide economies of size. For example, doubling output from 2.5 million broilers to 5.0 million

reduces equipment investment in these facilities by 25% per broiler marketed.

Technology Transfer Limits U.S. Exports

The technology for broiler production easily transfers, as has been shown again and again since U.S. scientific advances beginning in the 1940s allowed confinement production of poultry. These scientific advances gave U.S. farmers an early export advantage. Before U.S. agribusiness began exporting this broiler production technology in the 1960s to Western Europe and Japan, U.S. exports were more than 30% of world chicken meat trade. Though U.S. chicken meat exports are larger now than in the 1960s, the U.S. share has been cut nearly in half, to 17% (FAO).

The U.S. chicken meat exports to Europe began to decline with the technology transfer in the early 1960s as Dutch exports replaced U.S. exports to West Germany. Broiler production continued to increase in the European Community (EC), outpacing consumption. Now, led by France, the EC is a leading exporter of chicken

Table 1. Investment Breakdown for an Integrated System Producing 2.5 Million Broilers Annually

Facility	Total Investment by Facility	Investment for the Equipment
	(U.S. \$)	
Feed mill	300,000	150,000
Breeders	650,000	65,000
Hatchery	590,000	295,000
Growout	2,900,000	290,000
Processing	1,060,000	265,000
	5,500,000	1,065,000

Note: Adapted from the World Bank.

meat. France used government subsidies to establish broiler operations in Brittany because of that region's high unemployment (U.S. Department of Agriculture, FAS).

Japan's chicken production began rising with the transfer of broiler technology in the late 1950s. Consumption, however, outpaced local production because limited agricultural land and high population density restricts broiler production and processing. Thus, Japan remains a chicken meat importer from the United States and Thailand, and recently from Brazil.

Thailand began modernizing its broiler industry in the early 1970s. Although Thailand's production costs once were an estimated 30% higher than in the United States, imported technology and reorganizing producers from independent growers into integrated companies similar to those in the United States narrowed the U.S. advantage (U.S. Department of Agriculture). Using its low-cost labor to compete with U.S. exporters, most of Thailand's exports are deboned broilers to Japan.

Brazil also began exporting chicken meat in competition with the United States in the early 1970s, principally to the Middle East. Poultry production technology and organization in Brazil is similar to that of the United States. However, until 1988, Brazilian exporters benefitted from low-interest government loans and export subsidies (Ahmed). Although Brazil is now self-sufficient in poultry feed, many developing countries with rapidly increasing livestock production have had to import feedstuffs.

Chicken Production Often Leads to Imported Feed

Except in a few densely populated areas where shortage of land and pollution problems limit poultry production, the question of whether to import poultry meat or to build up a domestic poultry industry, even if feed must be imported, has generally been answered in favor of the building up of the poultry industry. The use of modern systems is higher in the Middle East than elsewhere in the third world because broiler production is relatively new in the region. Much of the region's poultry industry developed as incomes in the region rose following the high 1970s oil prices. The industry was created using the best technology, often transferred in large turnkey projects including the feed mill, breeder farms, hatchery, growout houses, and processing fa-

cility. One manufacturing company alone reported over 100 turnkey projects in the Middle East and North Africa from 1975 to 1985 ("Big D Achieve . . ."). A few countries provided incentives for this technology transfer. Saudi Arabia, for example, subsidized corn and soybean imports for broiler production.

Broiler production has also been growing rapidly in the developing countries of the Far East as incomes rose with exports of manufactured goods. In the Far East there was less importing of turnkey projects, more a steady upgrading of existing breeder and growout operations and shifting from live-bird markets (with on-the-spot slaughtering for the consumer) to factory processing.

The consequences of rising broiler production for feed trade vary. Many of the nations in these regions lack adequate cropland or suitable high-yielding crop varieties, requiring feedstuffs imports (fig. 2). For example, as the arid Middle East and North Africa reduced their dependency on chicken imports, dependency on feed imports increased. Elsewhere, even in countries in the Far East with abundant rainfall, feedstuff production is also often inadequate. For example, Malaysia's cropland and climate is not suitable to grow enough corn and soybeans, so the country must import part of its feed needs.

Without imports of feed ingredients, poultry producers in many of the countries in these regions, and elsewhere in the third world, would have to rely on high-cost locally grown feedstuffs, slowing the expansion of their broiler industries. Availability of low-cost feedstuffs is critically important. Feed will be 70%–80% of the total production cost of a broiler.

Poultry Trade Is Limited

One consequence of the easy and widespread transfer of confinement poultry production is that only 3%–4% of world poultry production is traded (fig. 3). This percentage is lower than the 15%–20% for some individual crops. Because crops are dependent upon both climate and suitable land, and not all countries are blessed with suitable resources, crop trade is greater.

Summary

Chicken meat consumption has grown very rapidly with rising incomes in the more prosperous

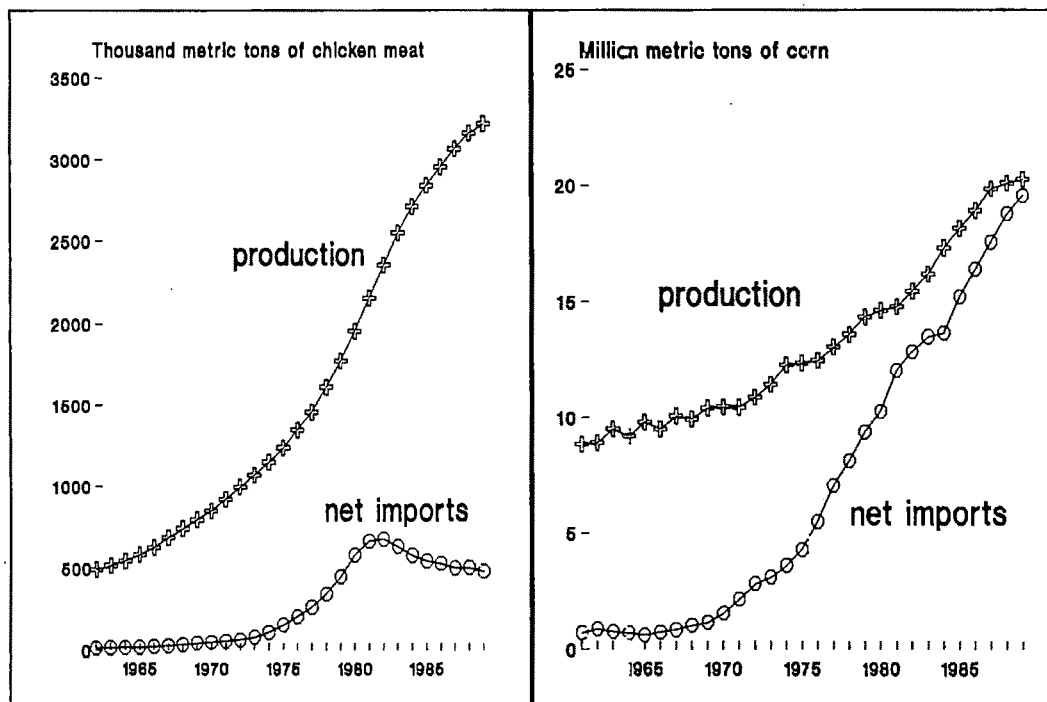

Figure 2. Production and trade of developing countries of the Middle East, North Africa, and Far East that import chicken meat (FAO)

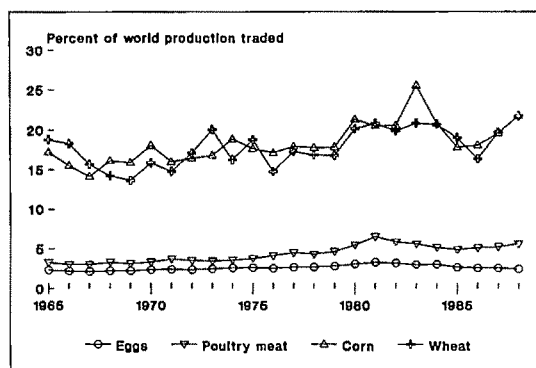

Figure 3. The percent of poultry production traded is less than crops (FAO)

developing countries, initially increasing imports of chicken meat. However, with rising consumption, incentives arise to import the technology to increase domestic production of chicken meat. This domestic production then substitutes for imports, slowing and sometimes reversing chicken meat trade. However, this transfer of technology often contributes to in-

creased imports of grains needed for modern livestock production.

International Capital Markets and Interest Groups

Terry Roe

Capital market integration has increased the scale and mobility of capital movements within and among nations to unprecedented levels. Integration is fairly recent. Frankel concludes from his review of the literature that barriers in the major world financial markets were sufficiently low that by 1989, financial markets could be viewed as being fully integrated.¹ The scale and mobility of capital flows among nations has numerous implications to currency values, interest rates, wealth, and, through current capital account linkages, to relative product and factor prices. Capital flows that have real economic effects also affect the functioning of policy instruments and how effective they are in remunerating an interest group at the expense, if any, of others.

This paper provides insights into the process and linkages by which the integration of capital markets has altered economic policy through interest group pressures on government. If economic policy is viewed as the outcome of interest groups seeking through the power of the state that which cannot be provided by the market alone, then capital market adjustments that affect the return to policy instruments can also affect the returns to lobbying resources and, hence, the balance of political influence among the various groups.² This type of explanation for economic policy has been forwarded under the rubric of models of "rent seeking" (Krueger 1974).³

Terry Roe is a professor, Department of Agricultural and Applied Economics, University of Minnesota.

¹ However, evidence suggests that increased volatility in foreign exchange markets has tended to mask comparative advantage in the case of some countries and limited the degree of integration for financial instruments of longer duration (Artis and Bayoumi).

² Lobbying is used as a surrogate for voting, donations to political action committees, and other means of influencing a government's choice over policy instruments. The key point is that resources are required to influence choice and that interest groups behave according to what they perceive to be in their own self-interest.

³ Other labels are "directly unproductive profit-seeking activity" (Bhagwati) or more generally "political economy" (Colander). Because numerous guides to this literature can be found easily, we provide no review here.

The paper is organized as follows.⁴ Selected historical evidence linking capital markets to pressures for legislation in the United States and other countries is briefly reviewed. In some cases, capital market adjustments have eased pressures for protection, while, in other cases, adjustments either forced policy change because of a liquidity constraint or made unprofitable the lobbying for sustaining policy in face of these adjustments. The discussion in the next section provides deeper insight into capital market-lobbying linkages. Discussion focuses on the results from a simple model of rent seeking, where government intervenes in markets and provides sector-specific public goods.

Interest Groups and Capital Market Adjustments: An Overview

The linkage between the overvalued dollar during the Bretton Woods period and the development of agricultural policy was discussed by Schuh in his seminal paper on exchange rates and agriculture. Under Bretton Woods, the overvalued dollar served implicitly to tax producers of agricultural tradables. Farm organizations grew into potent lobbying groups during this period. Their success in obtaining legislation to support farm incomes is evident. The influence of capital markets on pressures for farm legislation during the pre- and post-Bretton Woods periods has also been linked. In a study of the origins of legislation to protect farm incomes, Goldstein concludes that the economic environment of the 1920s helped motivate the formation of agricultural lobbying groups when it became generally apparent to rural groups that the post-World War I economy was discriminating against agriculture relative to other sectors of the economy.

⁴ See the background paper to this article by the same title for a discussion of capital market integration and current-capital account linkages in an open capital market economy.

In a review of the post-World War I economy, Orden suggests that these pressures would likely have been even stronger had capital markets not alleviated the otherwise larger appreciation in the U.S. dollar in response to reparation of European debt. Following World War I, capital markets provided reverse capital flows from the United States to Europe. If these reverse flows had not occurred, Europe would have maintained an even larger trade surplus. The U.S. dollar would have appreciated even further to restrict U.S. exports thus placing an even greater implicit tax on U.S. agricultural exports.

The effectiveness of capital markets to meet U.S. demand for loanable funds in the late 1980s has helped the United States sustain its budget deficit, albeit with the burden that debt service payments eventually imply. The burden of servicing increasing debt can be accomplished by a real depreciation of the currency, and/or a recession that reduces imports. If investors perceive an increase in exchange rate risk, real interest rates could rise. Perhaps equally alarming, the outstanding debt decreases the flexibility to respond to a recession because lowering taxes or increasing expenditures contributes to debt and threatens the willingness of investors, at the margin, to hold or accumulate more of the country's assets. Federal Reserve policy is also constrained because expansionist monetary policy will tend to depreciate the currency and raise inflation fears, while lower interest rates would contribute further to a decline in foreign capital inflows.

Were special interests cognizant of these factors while lobbying for policies that prevented adjustments in the budget deficit? Capital inflows possibly lessened pressures for additional farm subsidies. Still, the high real interest rates and the value of the dollar contributed to a decline in land values and a decline in the U.S. share of world agricultural trade. Legislation in response to these developments included the Export Enhancement Program. Ironically, as the 1990 farm bill suggests, the implication of growth in the U.S. budget deficit for action under Gramm-Rudman⁵ and higher taxes appear to have altered the political balance to favor a decrease in income support to agriculture, in spite of the apparent unwillingness of the European Community (EC) to liberalize agricultural trade sig-

nificantly.⁶ Hence, it seems reasonable to infer that world capital markets allowed the United States to delay adjustment to its growing budget deficit. Then, given the magnitude of the deficit, the rather modest adjustment that occurred led to a trade-off among special interests that induced the United States to partially liberalize agricultural trade.

Empirical support for the hypothesis that a strong dollar has precipitated protectionist legislation in the nonagricultural sector of the U.S. economy is judged by Leamer as less than conclusive. Perhaps the strongest evidence linking protectionist legislation and the appreciation of the U.S. dollar is provided by Grossman's study of the U.S. steel industry. Grossman finds that the steel industry's request for trade protection coincided with an appreciation of the dollar. The appreciating dollar and the corresponding loss of competitiveness was found to account for over one-half of the approximately 16,000 jobs lost in the industry.

The linkage between capital markets and interest groups is perhaps more evident in developing countries that have pursued inward-oriented economic policies (Balassa 1986). The World Bank-sponsored study of the political economy of agricultural price policies in eighteen countries found that an overvalued currency tended to account for larger indirect taxes on producers of agricultural exports than taxes imposed by interventions in the sector alone.⁷ Countries with higher indirect taxes were associated with those that exercised control over capital markets and pursued various types of exchange-rate-control regimes. Korea and Malaysia, whose capital markets were relatively open, tended to discriminate far less against agriculture than did the other countries (World Bank).

Controls on domestic capital markets are typically coincident with import-substitution-industrialization policies. Interventions in domestic capital markets have given rise to negative real interest rates in part because nominal rates re-

⁶ Johnson, Mahe, and Roe found support for the hypothesis that U.S.-E.C. agricultural policies pursued in 1986 could be characterized as Nash equilibria. A movement from observed policies, while saving resources, made both "politically" worse off as measured by an empirically estimated policy goals function. Preliminary results for the 1988 base year suggest the same conclusion. A departure from this equilibrium is possible if interest group pressures increase the political importance of the budget relative to income transfers to farmers, as the new legislation implies.

⁷ See Kueger, Schiff, and Valdes for a synthesis of some of the results of these studies. Individual country results appear in the World Bank's "Comparative Country Study Series on the Political Economy of Agricultural Pricing Policies."

⁵ See the 1990 Budget Reconciliation Act for the modifications to the 1990 farm bill.

main fixed during periods of high inflation. At various times during the 1970s, negative real interest rates were particularly large in Brazil, Ghana, Jamaica, Nigeria, Peru, and Turkey. The experiences documented by Balassa (1984) for Brazil and Turkey and by Corbor, deMelo and Tybout for the Latin American countries of the Southern Cone support the view that the effects of below-equilibrium real interest rates tended to lower the efficiency of investment by discriminating among capital users, to favor the allocation of rationed capital to capital-intensive techniques, to discourage domestic savings, and to encourage capital outflows.

Reform in many countries included in the IBRD study was forestalled when rising world prices for exportables increased liquidity. The constituencies supporting trade regimes became entrenched. When adjustment was needed, negotiations between various interest groups either proceeded slowly or did not occur in time to alleviate a liquidity crises. The result for many countries was an externally devised liberalization program that likely would not have come about from a realignment of interest groups alone.

The balance of political power to influence policy in most of these countries appeared to be urban based. Urban-based coalitions tended to support the use of the exchange rate, the trade and payments regime, and schemes to allocate credit at low nominal and negative real interest rates, all of which tended to discriminate against agriculture.⁸ If domestic capital markets had been open to world markets, exchange rate adjustments would have at least partially undone the objectives of sector interventions because currency depreciation would have raised the real price of food to consumers and adjustment in relative prices would have decreased the discrimination against agriculture relative to the nonagricultural sector.

There are both economic and political equilibria. An extraordinarily large economic adjustment that may lessen market distortions may so threaten or realign the balance of political influence that investors (asset holders) perceive increased risks to political stability and to asset returns. This tendency, coupled with the increased investment opportunities created by the ever more integrated world capital markets, likely increases the incidence of capital flight.⁹ Hence,

the increased capacity of world capital markets to more cheaply and quickly supply capital to perceived investment opportunities can increase both the cost of realigning economic policy and the cost of policies that induce domestic market distortions.

A More In-Depth, Narrow View of Special Interests and Capital Markets

To provide some insight into the economic forces that influence political equilibria, it is useful to structure the discussion around a model of rent seeking. Even though the model excludes capital markets and imported intermediate capital goods, some implications of the current account–capital account linkages to the welfare of households can be discerned. The model resembles that of Young and Magee, except for purposes here, we focus on the individual household and treat the political process as a black box.¹⁰ Consider a small two-sector economy that produces and consumes an export and an import good using only labor L_i , a sector-specific factor x_i , and a sector-specific public good G_i , where the sector index is $i = r$ (rural), u (urban). The government's policy instruments are the relative price p of the export good and the production of public goods using the technology $G_i(l_i^g)$, where l_i^g denotes government hired labor. The price of the import good is *numéraire*.

Let the typical household's "conditional" indirect utility function be denoted as

$$(1) \quad V_i[p, \pi_i[p, w, c_i, G_i] + w(\bar{L}_i - l_i) + c_i \bar{x}_i + \gamma_i T[G, p, p^w]],$$

where $\pi_i(\cdot)$ is the indirect profit function; w and c_i are wages and the price of a factor that is only traded within the sector (e.g., land), labor and sector-specific endowments are \bar{L}_i and \bar{x}_i , respectively; γ_i is the proportion of the total tax bill T paid by the i th household; and p^w is relative world market price.¹¹ Taxes depend on the government's expenditures on public goods G_i and the fiscal costs associated with interventions that cause a departure between domestic and

sued. Uncertainty as to whether a new regime can be sustained leads asset holders to slow the repatriation of flight capital from markets outside the country.

¹⁰ The framework is adapted from Roe and Graham-Tomasi. They provide a more detailed specification of the political process and show the derivation of the type of results reported here.

¹¹ The tax equation prevents the government from obtaining "free" resources from the rest of the world.

⁸ See Greene and Roe for the case of the Dominican Republic.

⁹ Dornbusch's study of the Mexican experience with stabilization policy strongly suggests a political motivation for the policies pur-

world prices. The function is referred to as conditional since the lobby level l_i is the remaining variable to be chosen. Presumably, lobbying influences the government's choices, G and p .

Before the household can optimally choose l_i , it is reasonable to assume that it holds beliefs about the response of the political process to its lobbying efforts. That is, the household must hold beliefs about the government's policy decision rules. Let these rules be denoted as

$$(2) \quad p = p(l_r, l_u; Z),$$

$$(3) \quad G_i = G_i(l_r, l_u; Z)$$

where Z denotes a vector of exogenous variables, such as world price p^w , and resource \bar{L}_i , \bar{x}_i , institutional and political endowments, and so on. In general equilibrium, factor prices w , c_i are endogenous, they depend upon p , p^w , G_i , the other mentioned exogenous variables.

The necessary conditions for l_i to maximize (1.0) appear in table 1. Essentially, the condition indicates that l_i is chosen to equate marginal returns with marginal costs. To illustrate, consider term 1. If the rural household produces in excess of own consumption q_{rr} , ($y_r - q_{rr}$) positive, and its lobbying efforts result in an increase in the price of y , relative to the urban good, $\partial p / \partial l_r$ positive, then the household realizes a gain from lobbying. Thus, the more specialized is the household, y_r large relative to q_{rr} , the more willing it is to allocate resources to

influence price policy, all else constant. The availability of a cost-reducing technology G_r , term 3 positive, also increases the household's willingness to influence policy.

The trade-off between rural and urban households can be seen by considering the equivalent of term one for the urban household. This term can be shown to be $-q_{ru} \partial p / \partial l_u$, where the urban household lobbies for a decrease in the price of food, i.e., $\partial p / \partial l_u < 0$. Hence, all else constant, rural households have an incentive to lobby for an increase in the price of the rural good while urban households have an incentive to lobby for a price decrease. Depending on the sign of $\partial^2 p / \partial l_i \partial l_j$, they may also be willing to countervail the lobbying efforts of the other. A prisoner's dilemma is one possible outcome.

If $(\bar{L}_r - L_r - l_r)$ positive, rural household labor is employed in the urban sector. In the Ricardo-Viner type of model specified here, a component of the derivative dw/dl_r is $\partial w / \partial p (\partial p / \partial l_r)$ where $\partial w / \partial p$ is positive. Then, the household has an additional incentive to lobby for a price increase since real wages rise. If another freely mobile input were specified, then the sign of $\partial w / \partial p$ depends on the Stolper-Samuelson condition.

A number of points can now be made. First, even though capital markets do not appear in the model, it can be seen that current and capital account linkages that affect relative prices of commodities or factors can induce households

Table 1. Necessary Conditions for Determining the Household's Willingness to Pay to Influence Economic Policy

Term 1, ^a Commodity Market		Term 2, Labor Market		Term 3, Public Good
$(y_r - q_{rr})p_{lr}$	+	$(\bar{L}_r - L_r - l_r) w_{lr}$	+	$\pi_{r,G_r} G_r, l_r^g, l_r$
The product of household production y , less consumption q_{rr} , i.e., market surplus, and the change in price p from additional lobbying l_r .		The product of the household's net labor positions and the indirect effect of the change in wages w from additional lobbying l_r .		The product of the shadow price π_{r,G_r} of G_r , its marginal product G_r , l_r^g , and the change in the amount of government labor employed, l_r^g, l_r .
Term 4, Sector Specific Factor Market		Term 5, Taxes		Term 6, Opportunity Cost of Lobbying Res.
$(\bar{x}_r - x_r)c_{r,l_r}$	+	γT_{lr}	-	$w = 0$
The product of the household's net employment position of the sector specific factor and change in its price from additional lobbying		The change in the household's tax bill from additional lobbying.		Wage, the opportunity cost of lobbying.

Note: See Roe and Graham-Tomasi for the details of this derivation.

^aNotation p_{lr} and π_{r,G_r} , for example, denotes the partial derivatives $\partial p / \partial l_r$ and $\partial \pi_r / \partial G_r$, respectively.

to alter their lobbying levels depending on their preferences, distribution of endowments, and the competitiveness of one sector relative to the other. Effectively, they act as though they choose l_i to re-equilibrate the first-order marginal return–marginal cost condition.

Consider, for example, the sector-specific factors such as land, plant and equipment, term 4. Policies that have an adverse impact on the value, c_i , of sector-specific endowments can also have an adverse impact on the sector's capacity to invest when \bar{x}_i meets collateral requirements. Policies that discriminate against agriculture can implicitly decrease its capacity to obtain credit relative to protected sectors. Further, just as the value of protection gets built into the value c_i of sector-specific assets, so too do the effects on c_i attributable to the performance of capital markets. Rent is $\bar{x}_i c_i$, which determines the value of this asset and, hence, wealth. If \bar{x}_i were plant and equipment of a sector protected using capital market controls of the nature mentioned, then liberalization can imply a decline in wealth of large magnitudes. If the household correctly perceives this possibility, then it may be willing to increase significantly its lobbying commitment to preclude such an eventuality. The distribution of endowments \bar{x}_i within the sector will also affect households' willingness to lobby differentially, depending on whether they are net suppliers or demanders of the sector-specific asset, $(\bar{x}_i - x_i)$ positive or negative, respectively. This has implications for sustaining a coalition.

Second, because the capacity, particularly of developing countries, to provide public goods (infrastructure, communications, education, public services) often depends on their ability to obtain loanable funds from abroad, domestic policy that gives rise to an efficient allocation of the country's resources is likely to increase its capacity to access international capital markets. The provision of public goods increases the productivity of private sector resources and the willingness of households to invest in quasi-fixed factors of production.¹² Countries following inward-oriented economic policies often incur substantial fiscal deficits, so that the marginal social cost of an incremental investment in public goods is extraordinarily high, all else constant. Further, public good allocation tends to have an urban bias (Braverman and Kanbur).

In this case, the framework posited in table 1 suggests that the household is concerned with

the optimal allocation of its lobbying resources so that, at the margin, it does not necessarily prefer the provision of public goods over policies that distort prices. In this case, the short-run marginal cost–marginal return to the household's lobbying resources might favor lobbying for price distortions as opposed to lobbying for the provision of public goods, particularly when households do not have access to world capital markets so that the provision of public good must be financed from domestic savings.

Three corollaries follow. First, to the extent that world capital markets have increased the incentive for capital to flee inward-oriented economies, then the cost of pursuing an inward orientation is increased further because, all else constant, the difficulty of financing the provision of public goods is increased as a result of the decline in domestic loanable funds and the adverse impact on imbalances in external accounts that capital flight implies. Declines in the provision of public goods clearly has dire implications for economic growth.

A second corollary of this argument is that when capital markets work imperfectly, as they almost surely did when many countries accumulated debt levels that later led to liquidity problems, households may view the tax component T in table 1 to be relatively unaffected by lobbying efforts, at least in the short run. Households may then continue to lobby for policies which, for some sustainable period, allow expenditures to exceed income. Effectively, governments, responding to the influence of special interests, may then pursue policies as though a financial constraint was not binding.¹³ The eventual burden of servicing external debt, as appears to have happened for many countries, has forced them to liberalize trade and other policies that contributed to domestic distortions. But, capital inflows to these countries have not returned (IMF). They now find themselves in a position where policy liberalization has occurred but implicit taxes on the consumption of traded goods is higher than it would likely be if capital inflows returned, i.e., their currencies are undervalued. Moreover, the cost of loanable funds to allocate to the provision of public goods is also higher in this environment.¹⁴

A third corollary is that the biased provision

¹³ See Mohtadi and Roe for the implications to economic growth when households ignore the tax implications of their lobbying activity.

¹⁴ An interesting conjecture is whether this line of reasoning also applies to the problems the U.S. will face in maintaining investments in public goods while servicing debt.

¹² See Binswanger for estimates of the effects of public good supply on the aggregate elasticities of agricultural supply.

of public goods can increase the willingness of the sector receiving more than its share to lobby for its differential advantage. The provision of the public good increases the willingness to invest in quasi-fixed factors of production, which, in turn, increases the first component of term 1; and, depending on the economies of scale of private and public goods in production, it can also increase the shadow price of the public good in term 3, table 1. Thus, the biased provision of public goods can increase the capacity of one sector to lobby for policy that further discriminates against the other sector.

The third point relates to the diversification of household assets and the functioning of domestic markets. This point also relates to Mancur Olson's suggestion that broad-based coalitions tend to take into account the adverse macroeconomic effects of their lobbying efforts so that the adverse effects of the differential advantage they seek tends to be less than those of narrow-based coalitions. The simple model in table 1 shows that, if households hold shares in both sector's sector-specific assets, then the household would have less incentive to seek its differential advantage because lobbying that benefited one sector at some cost of the other would be borne by both households. Households would have a greater incentive to cooperate, i.e., to lobby in ways that benefit both.

Capital markets permit households to diversify assets. In the presence of security markets, households can hold shares in the assets of other sectors and other countries, both directly and through retirement funds managed by capital market firms. Through diversification, these markets help households insure against policy (i.e., the influence of special interests) that adversely affects a sector or country. Hence, it can be conjectured that, all else constant, diversification increases the household's perceived cost of seeking its differential advantage. In terms of the simple model, the household may find it optimal to lobby for the provision of public goods as opposed to price distortions.¹⁵

The fourth point is closely related to the above. It deals with the presence of a lobbying equilibrium. More specifically, the seeking of differential advantage can be characterized as a non-cooperative game. A Nash solution can be

defined as

$$(4) \quad \partial V_r / \partial l_{r|l_r, l_r^*, z} = 0, \partial V_u / \partial l_{u|l_u, l_u^*, z} = 0,$$

where l^* are values that maximize (1) and $l_i(\cdot)$ are the rules obtained from a solution to the condition expressed in table 1. Condition (4) characterizes a stable political process; it allows (2) and (3) to be stated as functions of exogenous variables only. Of course, there may not be a Nash solution, and if there is, it need not be unique, nor is it the case that Nash behavior is most natural here.

Institutions are important because they are a component of the political technology available to respective households, the black box behind this model. This technology is important in determining the nature of a political equilibrium, i.e., the lobbying levels for which neither household is willing to change. Note, too, the knowledge and information requirements of the household, the prerequisites for informed, rational choice. A competitive market model with no government is informationally efficient because households need to respond only to the information provided by price signals. However, in the case considered here, the household's decision-making problem is more complex because of knowledge of the political "technology," equations (2) and (3), the effects of lobbying on market-determined variables, w , c , and c_s , taxes T , and the countervailing lobbying of adversely affected households. As noted by others, e.g., Krueger (1990, p. 21) "when the costs of a policy are obscure, special interests in the private sector and government have a greater opportunity to use those policies for their own advantage without incurring the disapprobrium of voters and other politicians."

Concluding Comments

Integration of capital markets has increased the scale and mobility of capital movements within and among nations. This paper has attempted to provide some insights into the process and linkages by which integration has influenced interest groups and hence economic policy. It is suggested that capital market adjustments and pressures for farm legislation can be traced back to post-World War I, although similar evidence for the industrial sector seems less well documented. It is conjectured that the balance of political influence delayed adjustments to the emerging U.S. budget deficit in part because world capital markets supplied the U.S. demand

¹⁵ If sector-specific factors x_i can be freely traded and labor is permitted to migrate freely between countries at low cost, much as in the case of countries within the European community, then models of the type posited here indicate that returns to lobbying in a particular country that tax some resources relative to others tend to decline.

for loanable funds at low cost. When implications of the deficit became more apparent to a broader range of interest groups, then political balance favored a decrease in support for agriculture in spite of the EC's reluctance to liberalize trade to anywhere near the same degree.

The use of capital market controls to discriminate against agriculture is most apparent in many of the world's developing and newly industrialized economies. Had these economies been open to the world's capital markets, then domestic capital market adjustments would have at least partially undone the objectives of sectoral interventions, hence the motivation for special interests to lobby for capital market controls.

More in-depth insights, and insights supportive of the previous discussion, are provided using a simple model of rent seeking. Key points are that capital markets affect the value of sector-specific resources and, hence, the value of collateral and wealth as determined by these assets. Collateral is associated with investment and the productivity of variable resources. Productivity growth sets in motion a chain of events including higher returns to resources and the specialization and division of labor. This chain of events also alters a household's willingness to lobby. If policy discriminates against the sector, then this chain of events can induce households to lobby for the removal of distortions. The converse is also possible. Because capital market adjustments affect the wealth embodied in sector endowments, households may be willing to expend lobbying resources to resist those capital market adjustments that adversely impact on wealth, e.g., the protection overvalued exchange rates and negative interest rates afford the industrial sector of many inward-oriented economies.

Countries following inward-oriented policies often incur substantial fiscal deficits so that the marginal cost of an incremental investment in public goods is extraordinarily high. In this case, the marginal return-cost calculus of the household may favor lobbying for interventions that distort markets rather than for interventions that increase the provision of public goods. However, to the extent that capital markets have increased the incentive for capital to leave inward-oriented economies, the cost of pursuing an inward orientation is increased. Effectively, capital flight increases the likelihood of a binding liquidity constraint making the maintenance of an inward-oriented policy less feasible regardless of the willingness to lobby for their support, unless of course, autarky is preferable.

A corollary is that capital markets may make fiscal and trade imbalances appear artificially cheap, thus inducing some households to ignore the tax implications of their lobbying efforts.

Capital markets permit the internalizing of lobbying externalities when households rely on these markets to diversify their portfolios. Then, less incentive exists to seek a differential advantage since lobbying that benefited one sector at some cost to the other is borne by the household through its portfolio linkage. This effect, too, may be a two-edged sword if households are not fully informed. Capital inflows to the United States during the 1980s appear to have contributed to rising security prices. Did rising security prices lead to additional support for supply-side policies?

The rather complex and obscure dimensions of capital market effects on an economy surely increase the complexity for the household to lobby for policies that truly increase its welfare. When the costs of policy are obscure, the lobbying costs incurred by special interests tend to be lower because of the lack of countervailing efforts by others. Political technology, ideology, knowledge, and information are particularly important to effect rational choice and a balance of competition in the "market place" for public choice. Institutions, a public good, seem to be particularly important in this regard.

The evolution of world capital markets should, over time, decrease the incentives for interest groups to induce governments to pursue policies that discriminate in their favor. This is another way of suggesting that evolution will increase the difficulty of pursuing policies that cause an inefficient allocation of resources and that externalize costs to other countries. This evolution also increases the importance of international institutions and agencies to perform activities that permit markets to function efficiently, such as enforcing voluntarily negotiated contracts, provision of information, and regulating sources of instability. Finally, efforts to liberalize an economy may focus first on capital markets because these markets impact on the entire economy and because of the second-best problems associated with sectoral liberalizations.

International Capital Markets and Development Funds for Agriculture: Discussion

Ralph W. Cummings, Jr.

The contributed papers do an admirable job of describing the new environment which has emerged over the past quarter of a century in which developing countries can supplement their own resources by tapping the international pool of savings now available from a huge, well-integrated capital market.

Roe's paper provides a framework to analyze the conditions—checks and limitations—imposed on economic decision makers by the international capital market. He argues that the evolution of world capital markets should, over time, decrease incentives for interest groups to induce governments to pursue policies that discriminate in their favor. This evolution increases the importance of development agencies to support activities that permit markets to function efficiently. Economic equilibria are interdependent with political equilibria; economic reforms must be sensitive to political stability.

Vocke describes the transfer of intensive poultry production systems. These operate very much the same whether in the United States or Thailand. This is a clear case where international capital markets should be tapped directly.

The paper by Lele synthesizes an ambitious systematic examination, using detailed case studies rather than polemics or econometric manipulations, of the role of foreign assistance in development. It points out some of the shortfalls of foreign assistance, among which instability, unpredictability, and biasing of investment decisions to availabilities of funds from donors are prominent. It underlines how the debt crisis has severely curtailed the previously increasingly important net flows of private capital to developing countries.

As noted in Lele's paper, all is not well with

official development assistance. Private capital flows will have to start growing again if the demand from developing countries is to be satisfied. These papers have several implications for donors.

One implication is the need to get back to basics; that is, to look first to analyze whether countries have progressive agricultural sectors. One of the failures of our profession is that we have been unable to convince leaders in developing countries and in our own development agencies of the fundamental lesson that a progressive agricultural sector is the driving force for economic development.

A second implication is the need to improve stability in addressing comparative advantage in providing assistance to accelerate agricultural development. If countries have sound economic environments, they should be able to borrow for infrastructure, either from the international capital market (Roe notes that exchange rate uncertainties cause international capital markets to be reluctant to finance longer maturities) or from the multilateral development banks. If a donor country has a competitive advantage in supplying infrastructure, that should be expressed through competitive bidding.

Donors have a role in promoting a sound economic structure. Lele concludes that even small amounts of aid—given in the context of a sound policy environment for the development of physical, human, and institutional infrastructure—are far more effective than large amounts given without attention to the overall development policy. Roe argues that domestic policy that facilitates efficient allocation of the country's resources is likely to increase its capacity to access international capital markets.

Donors can divide responsibilities to promote economic reforms. The multilateral banks and other donors can provide loans to implement structural adjustments and focus on "big policy," that is, macropolicy. The comparative ad-

Ralph W. Cummings, Jr., is an agricultural economist with the Agency for International Development.

The views expressed in this discussion are the author's and do not necessarily reflect those of AID.

vantage of a bilateral donor like the Agency for International Development (AID) that gives a limited amount of assistance the old-fashioned way—as grants or as loans whose terms approximate grants—is in supporting analysis to ask questions and to provide answers about what to change and how to change it, with particular attention to “small policy,” for example, specific challenges such as facilitating technological change, private sector growth, and environmental responsibility (ensuring benefits for future as well as present generations). Roe points out that capital markets permit households to diversify assets; this should be encouraged because the differential advantage that broad-based coalitions seek tends to be less than that sought by narrow-based coalitions. Broad-based coalitions are more likely to support government expenditures for public goods. He also cites Krueger: “When the costs of a policy are obscure, special interests in the private sector and government have a greater opportunity to use those policies for this own advantage without incurring the disapprobrium of voters and politicians.” Improving the legal environment—commercial law, regulations, grades and standards, market information, property rights—may be a key way to stimulate broad-based private sector activity.

The systematic examination of the role of foreign assistance in economic development demonstrates that the United States has a clear comparative advantage in technology development,

particularly in human resource development, research, and training. Lele’s paper provides strong evidence of the important contribution to Asia’s economic successes, and, conversely, the absence of the contribution partially accounting for Africa’s failures. There are a number of studies which demonstrate over a range of countries and commodities that returns to research, if done well, are two to three times other agricultural investments. Advances in U.S. agriculture, making use of university, the U.S. Department of Agriculture, and private sector experience, provide an extraordinary example of the successful development and application of science and technology. And the United States can benefit from it. Generally, developing countries are reluctant to borrow from either private capital markets or multilateral development banks for human resource development. The benefits result after a long gestation period, but the costs come early. The private sector cannot easily recapture the costs. And the effort must be done right and sustained for at least ten to twenty years. Science and technology is what developing countries most need and what U.S. assistance does best.

Official development assistance is not expected to increase significantly. The newly emerging international capital market introduces a potentially very positive dimension to economic development prospects. All donors need to reconsider how they can best facilitate the contribution.

Books Reviewed

Anderson, Kym. *Changing Comparative Advantages in China: Effects on Food, Feed, and Fibre Markets*. Paris: OECD, 1990, 118 pp., price unknown.

This book was motivated by the enigmatic nature of the changing role of agriculture in China's modern economy. Much of Anderson's work over the course of his career has focused on the rise and fall of agriculture in small Asian countries, and this new book analyzes the big picture in Asia; namely, what does the future hold for Chinese agriculture? He argues that China is losing its comparative advantage in agriculture; but, in return, its comparative advantage in lightly manufactured products is increasing. These are long-term trends the author has identified, and he fully expects them to continue. He is not surprised by what he finds because he argues that China is following basically the same development path taken by other East Asian economies (e.g., Japan, Korea, and Taiwan).

Chapter 1 is an executive summary of the book. Chapter 2 provides the theoretical framework for the book's thesis. It offers an explanation of (a) "why the agricultural sector's shares of GDP and employment tend to decline as an economy grows" (p. 17) and (b) "why densely populated countries also tend to lose their agricultural comparative advantage as they develop" (p. 17). The explanation of (a) is much more complete than for (b). Anderson argues that in a developing economy, agriculture's share of national product normally falls because, first, productivity growth is faster in agriculture than manufacturing; second, demand for food grows slowly; third, growth in the rest of the world lowers the terms of trade for agricultural exporters; and, fourth, agriculture's share of tradables' production declines. He then argues that densely populated countries eventually lose their comparative advantage in agriculture because development increases the availability of capital and the ratio of capital to natural resources rises. Comparative advantages shift with changes in relative factor endowments. Drawing on empirical evidence from economies in East Asia that are more advanced than China, Anderson concludes that "these densely populated, resource-poor countries lost their comparative advantage in primary products at a relatively early stage of their economic development, and enjoyed an initial strengthening of comparative advantage in unskilled-labour-intensive manufactured products, such as textiles and clothing" (p. 27).

The objective of chapter 3 is to provide an overview of the trends and structural changes evident in China's economic growth since 1949. Statistics are presented in support of the argument that China's comparative advantage in agricultural products has

been declining for a long time. On the other hand, it is shown that comparative advantage in textiles and clothing has been strengthening. The comparative advantage in "other manufactures" shows no trend. These emerging trends are important not only for China but also for the rest of the world because, as Anderson's data shows, China is becoming more and more trade oriented.

The objective of chapter 4 is to examine the question of whether or not the rapid economic growth China experienced in the 1980s will continue. The author argues that "notwithstanding the economic and political instability of 1988-89, there are good reasons to assume not only that it will (continue to grow), but also that the relative openness of China's economy will continue" (p. 55). If current policies remain intact, then Anderson sees the role of agriculture declining in China's economy. "By the year 2000, farms will account for probably less than one quarter of GDP and half of all jobs, compared with around 30 percent and 60 percent, respectively, in 1987" (p. 76).

Chapter 5 speculates on how policy makers in China might respond to the loss of its comparative advantage in agriculture. He discusses price policy, foreign exchange policy, and policies affecting interregional trade. The overall conclusion of the chapter is that "the nonagricultural policy changes discussed here do little to raise one's hopes for China improving its agricultural comparative advantage in the longer run. If anything they tend to reinforce the likelihood that China will become increasingly more dependent on agricultural imports in the absence of intervention by the Chinese government to restrict such growth" (p. 94).

The purpose of chapter 6 is to review some of Anderson's previous (in his work with Rod Tyers) projections of China's future level of food self-sufficiency. In addition, this chapter evaluates the effects of China's economic growth on domestic and international markets for fibers. The overall conclusion is that "it is likely China's self sufficiency in agricultural products, particularly animal feedstuffs and natural fibres, will decline during the 1990s and beyond" (p. 107). Anderson suggests the impact of heightened Chinese imports on the international markets may be small because of the excess world capacity for food production, particularly in the United States.

To summarize, the overall theme of Anderson's book is that China's agricultural comparative advantage is on a downward trend. This is similar to the trend in Japanese agriculture described by Hayami in a book published a few years ago. While the falling comparative advantage theory may be an interesting hypothesis, Anderson's book falls short of rigorously

demonstrating this decline in the case of China. Nonetheless, the book is an ambitious and credible piece of work.

Hayami, Yujiro. *Japanese Agriculture Under Siege: The Political Economy of Agricultural Policies*. New York: St. Martin's Press, 1988.

Bouman, F. J. A. *Small, Short and Unsecured: Informal Rural Finance in India*. Delhi: Oxford University Press, 1989, xi + 145 pp., Rs 120.

Bouman presents a lucid description of rural finance in India. He chose the district of Sangli in the state of Maharashtra as the battleground for his research. The choice of Sangli is aimed at providing fresh insights into the dynamic relationship between finance and development in an economy that is "in a rapid transition from a subsistence to commercial orientation" (p. 2). This is one area where the book differs from the existing literature dealing with the same subject matter.

The main topics of the book are presented in a logical manner. The book starts with a general review of the debate between formal and informal finance. This is followed by a discussion of the Indian rural finance policy. It then proceeds with a description of the sugar boom in Maharashtra. The discussion of the rural financial markets in Sangli starts with a general description of the various financial agents, and then focuses on key players in the informal financial markets, such as the Urban Credit Societies (UCS), the *bishi* (ROSCA/RESCA), pawnbrokers, and milk collectors. The last chapter gives an evaluation of the relation between finance and development.

Evidence of the systematic bias of policy makers against informal finance in India are sprinkled in several chapters. Examples of these are the Moneylenders' Acts, the Debt Relief Acts, and the lack of appreciation by policy makers of voluminous studies on informal finance in India done by noted researchers. The discussion about the Indian rural policy looks familiar to those who come from low income countries. The policy consists basically of creating highly specialized financial institutions that give less emphasis to savings mobilization and concentrate instead on the delivery of cheap credit to specific sectors of the economy. An example is the Primary Agricultural Credit Societies (PACS) which "operate as retail agents of government loans for agriculturists" (p. 39). The result was the rapid proliferation of unviable financial institutions with some equity implications because "wealthier farms are often the main defaulters" (p. 115).

Against this background is the dynamism of the

informal financial agents which consist of less regulated (e.g., the UCS and licensed pawnbrokers) and completely unregulated agents (e.g., the *bishi*, unlicensed pawnbrokers, and milk collectors). Bouman reports they have proliferated even in areas where numerous formal financial institutions already exist. Their emergence can be attributed mainly to the failure of formal financial systems to respond to the growing and changing demands of people for financial services. For instance, beneficiaries of the sugar boom who "had money to spend and were looking for new production and consumption alternatives" (p. 4) formed their own UCS because "the existing financial institutions could not accommodate them" (p. 4). *Bishis* became popular because of "the high return they offer on savings and the relatively easy access they provide to credit" (p. 56). The milk collectors who became informal lenders supplied loans to less affluent farms who could not obtain loans from the formal financial institutions, thus enabling them to respond to investment opportunities brought about by the dairy boom.

The informal sector in Sangli proved to be resilient and innovative. The collapse of several UCS caused by political intrusions and fraud committed by some of their officers elicited some positive responses, such as appointing motivated professionals with experience in managing a financial institution. Old forms of financial arrangements became obsolete and were replaced by new ones in response to the changing requirements of the rapidly growing economy. A case in point is the gradual disappearance of rotating savings and credit associations (ROSCAs) and the emergence of RESCAs (regular savings and credit associations) in Sangli. One weakness of the former is that only one player can be accommodated at one time; and, even then, he "cannot be sure of the moment he will receive the fund" (p. 55) because of the lottery mechanism. In contrast, several borrowers can simultaneously be accommodated in RESCAs. Interestingly, the recently created *bishis* tried to deal with the problem of shortage of capital by collecting "large-sized one-time lump sum payments" (p. 67) as shares of members and also lengthened their life cycle so that they can provide larger and longer loans.

The last section in the book deals with some nagging questions that have been raised since the time when informal finance caught the attention of researchers and policy makers. One such issue is whether formal and informal finance are substitutes or complements. Bouman has pointed out that in a penny economy, small and short loans are widely demanded. "It is precisely this small-loan specialization which precludes the substitution of the informal lender with a supposedly more public-spirited formal institution" (p. 125). Another issue is the linkage between formal and informal financial institutions. He cautions those who are trying to forge such linkage through some policy design. According to him, "the Sangli experience demonstrates that linkages seem to develop spontaneously whenever and wherever peo-

ple perceive such links as advantageous. Without such advantages, any policy of link-promotion will be an uphill struggle" (p. 127).

As one goes through the book, he will be bothered by a number of issues. For instance, the author did not discuss how the sample financial agents included in the study were selected. This is important to dispel any doubt about the positive contributions of informal finance in the economy. While the author mentioned some cases in which some of his Indian friends were trying to prove the absence of relationship between informal finance and economic development by citing "hearsay scandals of bishis, insisting that bishi-loans stimulated alcohol abuse" (p. 120), he could be accused of exaggerating the existence of such relationship by conveniently selecting the sample; hence, the need to discuss the sampling procedure. Mention should also be made of the instruments used in gathering primary data, i.e., whether structured interview schedules were administered to the respondents.

The author has pointed out that the supply of formal and informal loans in Sangli has been growing substantially with economic development and indicated that there is sufficient competition in the market by just looking at the number of financial agents. Yet, he did not provide an analysis of the behavior of lending rates over time. One would reasonably expect that real interest rates have gone down over the years if competition really did improve. In fact, the author did not provide a good analysis of the structure of lending rates. This is most glaring in this analysis of *bishis*.

Despite these questions, the book provides valuable insights on rural finance. Policy makers in LDCs should find this book useful in their work. For students of finance and development in LDCs who have been exposed to the elegant models of financial institutions' behavior, the book is a good eye-opener.

Philippines Institute of Development Studies

Drèze, Jean, and Amartya Sen. *Hunger and Public Action*. Oxford: Clarendon Press, 1989, xviii + 373 pp., \$45.00, \$15.95 paper.

For those concerned with the alleviation of hunger in the developing nations through public action, this is a most important book. Hunger is defined as including famines and chronic undernutrition. Public action includes activities of both the state and individual members of society.

This is a big and challenging topic, but the authors are more than up to it. Drèze, a former lecturer in development economics at the London School of Economics, has extensive field experience in India. Sen, formerly Drummond Professor of Political Economy at Oxford and now Lamont University Professor at Harvard, is a brilliant polymath who has had a long-standing concern with hunger. They make a

formidable team. Their work was sponsored by the World Institute for Development Economics Research (WIDER).

The book builds on previous writings by both authors, particularly Sen's well-known *Poverty and Famines*. A companion three-volume set of readings edited by the authors, titled *The Political Economy of Hunger*, is being issued in 1991 by the same publisher. They have also done their share of reading: their bibliography extends some 77 pages and includes roughly 1,700 citations!

The text of the book is organized into four main parts. Part 1 provides background on "Hunger in the Modern World." Part 2, "Famines," reviews strategic and technical issues of famine prevention in India and sub-Saharan Africa. Part 3 is titled "Undernutrition and Deprivation" but is much broader in scope and might equally well have been called "Public Support Measures and the Quality of Life." Part 4 is a one-chapter summary emphasizing public action.

Overall, the authors state that "the primary focus of the book is on action, rather than on measurement" (p. vii). Hence, they have tried to make the discussion nontechnical and accessible. They have emphasized what can be done inside the country rather than through external aid. Public action of both a collaborative and adversarial nature is advocated.

They take a broad social security approach which separates the problems into two interrelated camps; those that can be handled through protection (famine), and those that can be handled through promotion (undernutrition). They view famine as a simpler and less pervasive problem than undernutrition; far fewer lives are lost to famine than to undernutrition. They see wages for the employable through public works programs, supplemented by relief for the unemployable, as the most promising way to tackle famine. In the case of undernutrition, they examine both growth-led and support-led security and provide a number of country examples of the latter.

The strengths of the book are many. It is well informed and well reasoned. It admirably combines great erudition with case studies and examples. It suggests, without "excessive shyness" (p. vii), practical courses of action. Everywhere it turns, it sheds new light and new insights. It is well organized, well written, and superbly produced (I did not spot any typographical errors). In short, it delivers, and in fine style.

Weaknesses are relatively few and may differ with the eye of the beholder. I think that the role of war and revolution in setting the stage for famine might have been given greater attention (brief mention on pp. 274-75). Also, the geographic and historical scope of the coverage of famines might have been broadened. While the alleviation of undernutrition is a much broader subject, I cannot help but feel that the authors went a bit overboard in most of part 3; undernutrition, as such, is given relatively little attention. Furthermore, the authors completely neglect the critical role that public agricultural research plays in expanding food supplies and lowering the per unit costs

of food production and consumption. Little is said, for either famine or undernutrition, about what can be done when governments are weak or chaotic, or of what the budgetary costs are likely to be (the latter subject is only briefly mentioned on pp. 251–52, 270).

But if some of these aspects might be more fully developed, it must be acknowledged that the authors and the subject have come a long way since Sen's 1981 book. The discussion that it engendered (especially in *Food Policy* since 1986) and further empirical work are reflected in a much better balanced and more informed discussion. The key role of production, for example, is given increased attention. This volume, in turn, may launch a new cycle of discussion and learning.

The result is a book that everyone concerned with hunger can read with profit. It will also help broaden and improve the vision of more general development specialists. It should, in short, make a major intellectual contribution to more enlightened public action to alleviate hunger in developing nations. It could, if read and heeded, change untold lives.

Sen, Amartya. *Poverty and Famines*. Oxford: Clarendon Press, 1981.

Eicher, Carl M., and John M. Staatz, eds. *Agricultural Development in the Third World*, 2nd ed. Baltimore MD: John Hopkins University Press, 1990, x + 550 pp., \$55.00, \$18.95 paper.

The first edition of this book was published in 1984 and received generally good reviews by Carruthers and Roumasset, among others. The publisher states on the back cover of the second edition that, "Twenty of the book's thirty-two chapters are new, treating such topics as the role of women in rural development and policy reform in Latin America, Africa, China, and the Soviet Union. The readings address two basic questions about Third World agriculture: what is the strategic place of agriculture in national development, and how can the development of the rural sector be accelerated?" Net changes to the book are significant and worthwhile, though several "new" chapters are by different authors on the same topics.

"This book is designed to be used as a text in beginning graduate courses in international agricultural development and as a supplementary text in general economic development courses" (p. x). I have used the first edition in a course on the economics of agricultural development and have found it to be a generally excellent selection of the existing literature, although not all desired topics were covered.

Interestingly, outside materials on food price policy, global food balances, and productivity by farm size, which I have used to complement the first edition, are included in the second edition in their entirety or as portions of chapters. In my view, these additions make the book even more useful as a text for a beginning graduate course on agricultural development.

The second edition is divided into five parts that are organized in much the same way as for the first edition. Part 1, an overview, has an excellent review by the editors of the evolution of theories and development strategies for agricultural development since 1950. New sections include a discussion of the development themes and empirical evidence introduced in the 1980s and lessons and insights for the 1990s. This chapter, like the introductions to each of the four remaining parts of the book, provides a good background, overview, and some synthesis of the concepts covered in the following chapters.

Part 2, "Historical and Theoretical Perspectives," now includes four chapters, as compared with the seven chapters in the previous edition. Material on community development and the political economy of Latin America as well as two comment chapters have been deleted. New material includes two chapters on agriculture in transition and its shift toward industrialization, both positive additions. The induced institutional model chapter, by Ruttan and Hayami, remains in the new edition (pp. 97–112). However, none of the new institutional economics literature has been incorporated into the materials.

Part 3, "Food and Agriculture Policy" (formerly "Policy Analysis in a General Equilibrium Framework") includes only four of the nine chapters found in the first edition. The new title for this part more adequately reflects the material included in both editions, and rightly so, since previous reviewers pointed out the lack of any equilibrium framework in the first edition. The five new chapters cover some of the same subjects but with much more relevance and usefulness for development economists and practitioners. Particularly important are the chapters by Schuh, discussing the new macroeconomic situation (pp. 140–53), and by Bates, covering the political framework for decision making (pp. 154–59). These add important dimensions and insights to improving our understanding of the context within which agricultural development and policy change must take place.

Part 4, "Transforming Agriculture and the Rural Economy," has not changed significantly in terms of subjects covered but, again, the net change is very positive. The important topic of women's role in development has been added, not as a formality, but in recognition of its importance for effective policy development and implementation. The chapter, "Reflections on Land Reform and Farm Size," by Binswanger and Elgin (pp. 342–54), also is a significant replacement for two previous chapters in this section. This also can be said for the chapter on rural financial markets by Adams and Vogel (pp. 355–70).

Finally, part 5, "Case Studies of Economic Policy

Reforms," highlights the recent experiences of Latin America (new chapter), China (updated by new authors), and the Soviet Union (new chapter) in implementing policy reforms. These should be of special interest to readers watching the very recent attempts to change economic policies in Eastern Europe. In the last two chapters, two well-informed Africanists (Eicher and Lele) provide useful insights on the challenges facing most African nations overcoming their agrarian stagnation (pp. 503–39).

Eicher and Staatz have done a commendable job of drawing relevant materials from the extensive agricultural and economic development literature. The second edition includes many chapters focusing on current policy and development issues. It would be very difficult to find a better collection of materials in one book to use as a primary text for a beginning graduate course in agricultural development or as a supplemental text for economic development courses. The main criticism of the revised book likely to emerge is that it reflects the current development community emphasis on private enterprise, privatization, policy reforms, new technology, and "setting prices right." Most of the radical or opposing views of the neo-Marxists, dependency theorists, and others are largely muted in the second edition.

Fleischer, Beverly, *Agricultural Risk Management*, Boulder CO: Lynne Rienner Publishers, 1990, xv + 149 pp., \$25.00.

Smidts, A. *Decision Making Under Risk*. Wageningen Economic Series No. 18. Wageningen, Holland: Agricultural University, 1990, 329 pp., price unknown.

The literature on risk analysis and management in agriculture since the late 1960s has been accumulating at an increasing rate. Benchmarks of this growth are contained in the overviews on the subject by Dillon; Anderson, Dillon, and Hardaker; and Barry. We need another benchmark of the risk literature that has been accumulating since Barry's book, for the most part in journals and conference proceedings. The book by Fleischer and the monograph by Smidts contribute each in its own way to satisfying this need, Fleischer for the nonspecialist and Smidts for the specialist.

The purpose of Fleischer's book is "to provide nonspecialists with a guide . . . to risk and risk management . . . instrumental in understanding . . . agricultural policy" (p. xiii). It can be characterized

by its nontechnical approach to the discussion of risk management and its primary focus on the relationship between risk management and agricultural policy. Fleischer first surveys the subject of risk and how managers respond to risk, enumerates risk management tools, indicating why each is used and its effects on risk management strategies, and finally relates these to government programs and policies. The fact that all this is covered in just 149 pages indicates the brevity with which topics are covered. This book is clearly intended for those with no prior knowledge of the subject of risk and its management.

The monograph by Smidt reports his thesis on the application of a "relative risk attitude" model to potato-marketing behavior of producers.¹ It is a very thorough technical treatment of several aspects of risk in decision making associated with a real-world situation. After describing the decision problem confronting farmers, Smidt reviews and evaluates the various theories used in decision making under risk, carefully integrates these theories into the relative risk attitude model, thoroughly assesses the methodological problems of measuring risk perceptions and assessing risk attitudes, and finally analyzes the results of applying his model and measurement tools to a multiyear marketing strategy. This work will be valuable to anyone contemplating the analysis of risk or risk management in agriculture and to those wanting more than a cursory introduction to the area.

While Fleischer's book is useful for the purpose for which it was written, probably too much was attempted in the limited space allotted for each topic. In the latter chapters, the treatment of some common tools for managing risk in agriculture, forward pricing, and the role of government commodity programs are well done and should be informative to the intended audience. The first two parts are structurally less sound. A book of this intent should bring some order out of the profusion of information on the subject that is available and present it in clear, concise, and unequivocal terms. This book does not do this. For this reason, and the notable lack of citations, the book will have limited use as a course text.

The review and evaluation of theoretical and risk attitude measurement concepts by Smidt are very well done. The treatment of both topics goes beyond that normally expected in a thesis. With a strong focus on a specific applications problem, Smidts critiques and evaluates relevant theory with considerable thoroughness, providing a sound basis for the hybrid approach used in his model. He also is as thorough in his development and testing of alternative numerical methods for applying his theoretical constructs to a survey of 250 producers over a two-year period. The final chapter on evaluation and conclusions by itself is well worth reading and along with the chapters on

¹ "Relative risk attitude" is a theoretical bridge between Bernoulli's "strength of preference" approach and von Neuman-Morgenstern's "indifference utility" approach first introduced by Bell and Raiffa in 1982.

theory and methodological development provide a great deal of useful information. Those involved in studying more than just the theory of risk management and analysis will find this work to be helpful.

Although neither of these works completely satisfy the need for a benchmark book on risk, both in their own way do some of the job until one comes along. In particular, both have excellent bibliographies that capture the literature as it currently exists.

- Wädekin, Karl-Eugen, ed. *Communist Agriculture: Farming in the Soviet Union and Eastern Europe*. London and New York: Routledge, 1990, xviii + 331 pp., \$112.00.
- Both of these books deal with Soviet agriculture and agriculture in other selected Eastern European countries with centrally planned economics. Each book is comprised of papers from two separate conferences dealing with Soviet and East European agriculture and agrarian affairs. The contributors to these books represent several disciplines including economics, history, geography, and political science and exhibit considerable competence in the technical, social, economic, and political aspects of agriculture and agrarian affairs in the Soviet Union and selected Eastern European countries. The purpose of both books is to represent the types of analyses needed to understand the changes in agriculture and agrarian affairs in the Soviet Union and some Eastern European countries which led to the type of agriculture these countries had in the late 1980s.
- The book edited by Gray is arranged in two parts. The first part is concerned with the organization and performance of Soviet agriculture. There are nine chapters in this first part, dealing with topics such as agricultural productivity trends in the Soviet Union compared with other centrally planned economies, costs of agricultural growth and development in the USSR, Soviet food imbalances, Soviet utilization of meat and dairy processing capacities, agricultural pricing and policy under Gorbachev, recent developments in the agricultural collective contract, recent changes in Soviet rural housing policy, and trends in Soviet dryland farming and soil conservation practices.
- The second part of this book consists of five chapters dealing with technologies and information which could be drawn upon by Soviet agriculture. In the first chapter of this part, chapter 10, the Soviet scientific and technical information system concerning agriculture is described and evaluated in terms of effectiveness. In the next chapter, the contents of Soviet writings on foreign agricultural experiences are analyzed for possible impacts on Soviet agricultural policies. The last three chapters deal with potential lessons for Soviet agriculture from the Bulgarian experience with centrally planned agriculture, private agriculture in other socialistic countries, and Hungarian and Chinese experiences. These latter three chapters provide some informative comparisons between Soviet agriculture and agriculture in other centrally planned economies.
- The book edited by Wädekin contains three parts. The first part, comprised of six chapters, considers the historical, environmental, and social background of agriculture in the Soviet Union. The eight chapters of the second part focus on the current agricultural and industrial policies in the Soviet Union and their impacts on agriculture. The last seven chapters of the book comprise the third part and deal with agricultural experiences in other countries with centrally planned economies and the implications of these experiences for Soviet agriculture.
- The six chapters which comprise the first part of the book edited by Wädekin address issues such as the role of agriculture in Soviet industrialization, land-use zones and soil degradation, technical efficiency in cotton production, new attitudes in rural areas, impact of the Chernobyl incident on the Soviet food supply, and structural contrasts and convergence in socialist and capitalist agriculture. These six chapters provide an excellent background for understanding Soviet agriculture. The next eight chapters analyze recent and current agricultural policies such as *perestroika* in agriculture, the March 1986 agricultural decree, uncertainties over reform, normative planning in Soviet agriculture, Raion agroindustrial associations in Soviet agriculture, organizational innovation in agricultural work, economies of small scale in Soviet agriculture, and private plots as system stabilizers. The third part of the book consists of seven chapters which are concerned with reforms in socialistic agriculture in Bulgaria, Poland, German Democratic Republic, and Hungary. In each of these latter chapters, attention is devoted to an analysis of major reforms in agriculture in the four selected Eastern European countries.
- These two books are useful references not only to

those interested in understanding agriculture and rural affairs in the Soviet Union and other Eastern European countries with centrally planned economies but also to those concerned with reforming or dismantling socialist agriculture in other parts of the world. These two books provide comprehensive analyses and information about various agricultural programs and policies in the Soviet Union and other centrally planned economies. Specific programs of various agricultural plans are analyzed and evaluated in terms of their physical, economic, social, and political consequences and their degrees of success or failure. The authors of the chapters in these books address why various agricultural programs did not work any better than they did and why many did not function as planned. These two books should be of interest to historians, political scientists, economists, and other social scientists concerned with socialistic agriculture and its role in planned economies.

Joseph Havlicek, Jr.
Ohio State University

Jackson, John H. *Restructuring the GATT System*. New York: Council on Foreign Relations Press, 1990, vi + 121 pp., \$14.95.

The importance of the General Agreement on Tariffs and Trade (GATT) for world agriculture has become more evident as a result of the recently completed Uruguay Round. As agriculture becomes more integrated into the GATT over time, agricultural trade economists will increasingly need to understand the history and inner workings of the GATT. This book, written by one of the leading legal scholars on international trade, serves as an excellent introduction to the topic.

As suggested by the title, the author espouses change in the GATT "constitutional" system. In the final chapter, he outlines a proposed charter for a World Trade Organization, a broad international commerce organization which would "serve and 'shelter'" other treaty instruments, such as the GATT. Its purpose would be similar to the non-GATT portions of the International Trade Organization (ITO) and to the Organization for Trade Cooperation (OTC), international organizations negotiated in the early post-World War II period but rejected by the U.S. Congress. Jackson's proposal should be taken seriously and warrants further attention. However, for most readers, the importance of the book will be its thorough and concise description of the GATT system as it has developed and now stands.

After an introduction, Jackson begins part 1, "The Defective Constitution of GATT" with chapter 2 on "The History and Perspective of GATT." This chapter examines the wartime and early postwar environment which led to the negotiation of a triumvirate of international economic organizations: the International Monetary Fund, the World Bank, and the ITO. Drafting of the ITO was completed in 1948 in Ha-

vana. The Havana Charter included agreements on economic development (including the regulation of foreign investment), restrictive business practices by private as well as public business (an internationally applied antitrust policy), commodity agreements and, notably, a well-defined organizational structure. However, the ITO was never approved by the U.S. Congress; and the GATT, designed to be subordinate to the ITO, continues to be applied provisionally. While Jackson describes the GATT as having been "much more successful than one could fairly predict in 1951 when the ITO idea died," he argues that the current constitutional structure of the GATT and its provisional application (which, for example, allows national policies predating the GATT to continue in force because of a grandfather clause) inhibited GATT's ability to deal with troubled industries such as textiles, agriculture, and steel.

The GATT "constitutional" structure itself is the topic of chapter 3. Here Jackson addresses the questions of GATT membership, voting rules, amendments, side codes (such as the International Dairy Arrangement), and the relationship of GATT and national legal systems. While these are potentially dry topics for economists, Jackson sprinkles his writing with examples and historical precedents which indicate the importance of these issues and expose the frailty of the current system. A short chapter on the history of GATT negotiation rounds, with special emphasis on the Uruguay Round, completes part 1 of the book.

In part 2, "Perspectives on International Economic Institutions," Jackson begins by discussing "The Jurisprudence and Policy of a GATT Constitution" (chap. 5). Some of the institutional problems of GATT that Jackson perceives include (a) the treaty structure, which remains provisional and allows some parties to question whether they are bound by GATT rules; (b) the amendment provisions, which make amendments exceedingly difficult and limit their application to countries which accept them; (c) a lack of clarity in the relationship of "side codes" to the GATT; and (c) the dispute settlement process.

The last of these is the major topic of chapter 6, "Rule Application and Dispute Settlement." Jackson notes disagreement over whether the goal of GATT dispute settlement procedures should be to solve the instant dispute (by conciliation, obfuscation, power-threats, or otherwise), or to promote certain longer-term goals. In making his case for adopting the latter objectives, Jackson carefully reviews the evolution and current state of dispute settlement under GATT. Complaints about the procedures are numerous: (a) they are slow; (b) a loser may block adoption of the resulting panel report; (c) it is sometimes unclear whether the GATT procedure or another procedure outlined in a "side code" is the appropriate one to follow; and (d) governments are often slow to implement any required changes. It is interesting that most cases are brought by industrial countries against other industrial countries; however, the markets in

question are often not industrial. Jackson notes that, especially with respect to the European Community (EC), agricultural products are often involved in disputes. The EC is virtually alone in its opposition to attempts to strengthen the GATT dispute settlement procedure, such as one outlined by the author. Jackson gives compelling reasons why neither disputant should have the right to block adoption of a panel report, as they currently can.

A particular future challenge for the GATT involves the integration of large centrally planned economies such as China and the Soviet Union. In chapter 7 the author argues that these countries should be allowed into the GATT (or some other world trading organization), noting the prevention of war was an objective of the postwar international economic system. This "universal approach" to membership will cause particular problems and require the development of an "interface mechanism." Arguing that it is not the purpose or role of the GATT to apply pressures on sovereign nations to accept market-oriented economic principles, he writes that interface rules should be designed under which the applicant non-market economy can trade with the existing GATT market economies to the most feasible extent.

The book concludes with a detailed plan for "Reforming the GATT System" in chapter 8. The charter for Jackson's World Trade Organization (WTO) would build on the existing GATT by providing an institutional structure for the GATT and other agreements while serving the institutional needs for service sector agreements. It would also implement new agreements (regarding, for example, intellectual property rights) resulting from negotiations under GATT, establish a centralized panel procedure for dispute settlement under GATT and the "side codes," and make explicit the relationship of other treaty instruments to the WTO.

Jackson's book will be of interest to economists and agricultural economists who want to learn more about the GATT and the international trading system. Although his proposal for reform in the last chapter is sketchy, he pinpoints many problems with the current system, and his proposal should provoke much thought and research.

Lobao, Linda M. *Locality and Inequality: Farm and Industry Structure and Socioeconomic Conditions*. Albany: State University of New York Press, 1990, xiv + 291 pp., \$16.95

Lobao takes on a massive task as her "book explores how the organization of economic production in farming and industry generates socioeconomic inequality across different localities in the United States" (p. 1). As such, it represents a significant contribution to an aging literature on farm structure and com-

munity relationships. The book would contribute to a graduate course on farm structure or rural development. It is also important reading for scholars in these areas.

The major contribution rests with a challenge to traditional work following Goldschmidt, who tested the hypothesis that communities influenced by small farms are better bastions of democracy with improved quality-of-life than are communities influenced by large farms. Goldschmidt used a case study of two communities in California to support this hypothesis. Lobao builds on work for the Office of Technology Assessment (see Swanson) to examine the Goldschmidt hypothesis.

Lobao devotes three chapters (2-4) to reviewing literature and building toward a theoretical framework for her empirical tests. Her critique and integration of many conflicting paradigms is particularly noteworthy. I found these chapters informative and well-developed. She reviews both the sociology and agricultural economics literature, bringing the reader up-to-date on the studies performed in this important area.

A major and significant theme in the theoretical development is that rural communities are influenced by many forces other than farming. Lobao elaborates: "I develop a conceptual framework that ties farming and industry structure and other structural factors to inequalities in socioeconomic conditions across localities. This involves the interplay of three sets of forces: economic structure, spatial or locational structure, and human agency in the form of characteristics that empower workers and the households. My perspective is developed through a synthesis of political economy and other structural approaches" (p. 5).

In chapter 5, she presents data that is subsequently used for analysis. Of note to the agricultural economist is the development of an index of farm structure. Building on work of Wimberley, Lobao develops indexes that capture differences "in farm organization, scale, and operator characteristics at the county level" (p. 98). Three patterns of farming are developed: (a) industrialized farming, (b) larger family farming, and (c) smaller family farming. Farm structure indexes are used with a variety of county data on industry structure, labor, spatial characteristics, and measures for inequality (e.g., median family income, poverty, income inequality, unemployment, infant mortality, etc.).

Chapter 6 presents national models, and chapter 7 presents regional models used to test hypotheses regarding community inequality. Because of data availability, the analysis is restricted to census base periods around 1970 and 1980. In addition to cross-sectional models, lagged models are developed to test how 1970 conditions influence 1980 measures of inequality. I was left wondering why the author did not expand these models to reflect some recent work using similar data (see Swanson). In this work the change between the two periods is modeled by taking the dif-

ference in both independent and dependent variables for the two points in time.

Generally, Lobao has numerous findings with regard to "locality and inequality." I shall focus only on the farm structure findings. An underlying theme of the book is that assumptions of a purely linear relationship between farm structure and community well-being or inequality should be challenged. Lobao recognizes work by Skees and Swanson that influenced her thinking in this regard. She summarizes her farm structure findings as follows: "This study provides limited support for the Goldschmidt hypothesis that industrialized farming reduces socioeconomic conditions across U.S. counties. But the detrimental impacts of this production system are neither automatic nor strong; further, they are not apparent at any particular historical point (cross-sectionally) in every region of the country This study also has shown that the effects of industrialized local farming are not predetermined but can be modified by nonfarm factors" (p. 213). She goes on to state "the findings with regard to smaller family farming indicate that the Goldschmidt hypothesis needs serious revision" (p. 214). In short, her findings demonstrate negative relationships between well-being measures and small and industrialized farming. "A consistent finding of this study is that a production system of family operated commercially-oriented farms—larger family farming—results in better socioeconomic conditions for localities" (p. 216).

At times, Lobao slips into a common trap of making too much of her model relationships as she leads the reader into thinking that cause and effect are being presented. However, in her conclusions she is very clear about this shortcoming of many of her models. She is to be commended for a massive undertaking and a significant contribution to a literature that has been lacking in its development.

This book is a collector's item. For almost six decades, the International Association of Agricultural Economists (IAAE) endeavored to arrange a professional conference in China. The preface to this book reports that the Chinese scholar C. C. Chang first proposed a China Conference during his visits with IAAE members in Europe in 1933. Chang's original travel objective of attending the IAAE meeting that year was frustrated because of its abrupt cancellation as a result of problems in the host country, Germany. Chinese participation in IAAE meetings was limited during the ensuing years. The conference finally became a reality in October 1987 when agricultural economists from fifteen countries gathered near Beijing for professional discussions with Chinese colleagues. This book is a record of the symposium, the theme of which was "Rural Development Strategies: Theory and Practice." Appropriately enough, an active participant in the symposium was C. C. Chang.

The symposium organizers planned for the presentation of fifty papers, half to be contributed by IAAE members and half by members of the Chinese Association of Agricultural Economists. The aim was for foreign participants to explain other country experiences with rural development. Likewise, the Chinese were to inform visitors about China's rural development. Most of the papers were presented in small groups with adequate time for translation and discussion. The small group approach encouraged frank discussion and exchange despite language and cultural barriers.

The book consists of an eight-page editor's introduction, fifty-one chapters, of which thirty-four are full papers and seventeen are one- or two-page abstracts, and a list of participants. Approximately thirty papers concern China directly, while the remainder summarize economic and rural development experiences in other countries, sometimes with explicit implications of those experiences for China. The papers presented by Chinese authors tended to be descriptive, while the non-Chinese authors often times presented theoretical work with some quantitative analysis. Only a few papers reported formal quantitative models.

Part I sets the stage for the book through three short papers written by Chinese authorities. These papers provide a brief rationale for the political and economic policies followed by China in the post-World War II period with particular emphasis on the landholding and agricultural marketing systems and a description of the key reforms associated with the household based contract responsibility system established in the late 1970s. The authors note the challenges currently faced by a country with more than a billion people, with less than one hectare of arable land per peasant household, and with a serious short-

age of physical infrastructure, institutions, and administrative ability.

Part 2 contains papers reporting on aspects of development experiences. The papers report the experiences of specific countries such as India, Korea, Japan, Eastern and Western Europe, and Israel. Other papers explore specific issues such as central place theory applied to Germany and the impact of trade and macroeconomic policies on agricultural growth as observed in several Latin American countries. A common theme linking many of these papers is the role of government policy in shaping the speed and pattern of the agricultural changes noted in the countries studied.

The third part contains fourteen papers under the general heading, "Recent Chinese Experience and Prospects for the Future." Common themes in these papers include past trends in agricultural production; average cereal supplies per capita; trends in population, labor force, and surplus agricultural labor; the impact of changes in policies beginning in 1980; projections of future supplies of and demand for food and agricultural products (usually without describing the methods used); and the need for more off-farm employment to absorb labor. One paper reported the results of analysis that showed substantial economic gains could be made through greater regional specialization in production based on comparative advantage.

One of China's serious shortcomings is poor infrastructure, especially transportation, which impedes greater regional specialization and interregional trade. Another problem concerns the future supply and use of chemical fertilizers. Two chapters in part 4 analyze infrastructure problems, and a third chapter discusses fertilizer supply and demand issues in comparison with the experience of India. Both countries have sharply expanded fertilizer use; but the methods to achieve this objective have been quite different, with China relying more heavily on public institutions to circumvent the shortcomings of market underdevelopment.

Four chapters in the next section deal with the subjects of rural investment and finance. They consider how agricultural investments have evolved and may be affected by the agricultural reforms that have sharply altered the urban-rural terms of trade. The control of investment funds has undergone a dramatic shift from central government to township and village enterprises. Enterprises and households now control larger amounts of gross domestic savings than the central government. The reforms made in the rural financial system to capture and allocate these savings are described.

Part 6 consists of seven papers grouped under the theme, "Ownership, Management, and Reward Systems." The papers examine the development of rural cooperatives, state farms, freshwater fish ponds, and the position and role of women in rural development. One paper compared the performance and incentive structure of Chinese and Canadian farms using the

entropy metaphor from systems theory. Another paper reports on an analysis of a sample of farms in Jiangsu Province designed to test the efficiency and equity implications of the household production responsibility system.

The final section, with eight papers, focuses on technology, research, and environmental issues. They cover the topics of technology transfer, research priority setting, farming systems research, information systems for microlevel decision making, and environmental issues associated with agricultural development. The paper on research priorities contains a preliminary analysis of the impact of agricultural commodity research in China, and discusses how different research objectives will alter the choice of commodities selected for primary research emphasis.

The papers in this volume present an insightful, albeit incomplete, view of the 1978 to 1986 developments that became known during the symposium as "China's Rural Development Miracle." The household-based contract responsibility system fundamentally altered producer incentives and sparked a rapid expansion in production, especially in the non-grain sectors. This pattern of decentralization of investment decisions is consistent with some of the rural development needs expressed in the symposium. First, off-farm employment opportunities will increase with the potential of absorbing some of the underemployed and unemployed rural labor. Second, increased local investments in rural towns and small cities may lead to a more socially desirable urbanization pattern than found in big cities in Western countries. But there are potential pitfalls as well. Pursuing regional self-sufficiency in the past in China is generally believed to have been enforced at a high economic cost. The poor state of infrastructure makes it difficult for China to now pursue the objective of specializing in regional comparative advantage under more liberal market conditions. Local decision makers who control more financial resources may choose to intensify growth and development in their respective regions and not invest in roads, ports, and communication facilities needed for expanded interregional trade. The development of financial markets to tap rural savings and facilitate the interregional flow of funds, improvements in tax collection and investments in public goods, and improved incentives for private infrastructure investment may determine if the short-term dramatic "development miracle" can be transformed into long-term sustainable growth.

John Longworth, Glenn Johnson, Theodor Dams, and Jim Hildreth of IAAE are to be congratulated for their persistent work with the Chinese authorities over several years to finally realize this symposium, and to help C. C. Chang achieve his dream. The papers in this volume are a tribute to their work. More important, the intense discussions held at the meeting and the circulation of the Chinese proceedings now underway in China may contribute in important unknown ways to the policy debates occurring in that country. We can only hope that the abrupt rupture in

international exchanges following the Tiananmen Square tragedy is only a temporary interruption of the exchanges between Chinese and foreign agricultural economists that began with so much promise in this symposium.

Pearce, David, Edward Barbier, and Anil Markandya. *Sustainable Development: Economics and Environment in the Third World*. Brookfield VT: Edward Elgar, 1990, vii + 217 pp., \$48.95.

As the development fad of the early 1990s, "sustainable development" may or may not deserve the attention of serious scholars. It is clear, however, that this particular idea has caught on among politicians and those who administer development assistance. The question remains, however, whether or not serious work by economists (or others) will have any impact on what the development community—and host governments—do with respect to natural resources in the tropics. The answer to that question, I suggest, depends upon whether or not the academic community is able to make meaningful programmatic sense out of the concept of sustainable development. The title and stated purpose of this book suggest that general goal.

We find here six chapters of reworked consulting reports and accounts of field work by the authors, preceded by three chapters that attempt to define the conceptual context for sustainable development. I first comment briefly on the six "empirical" chapters.

The empirical substance of the book consists of reports that appear to have been written for other audiences. These reports deal with (a) upland watersheds in Java; (b) forests on the outer islands of Indonesia; (c) the Sudan; (d) Botswana; (e) Nepal; and (f) Amazonia. The material in these chapters is descriptive as well as prescriptive. That is, certain natural resource situations are described and statements are made that, unless sustainable development practices are adopted, there will be hard times ahead. Policies in each country are discussed for their implications for sustainable development. There are useful data in these chapters and nice descriptions of specific resource problems.

Readers with experience in any of these countries are not likely to find much here that is not already well known to them. Yet, for the newcomer to natural resource issues in the developing world, this material will be most helpful in providing a perspective on certain problems.

But if the idea of sustainable development is to have any substantive impact on development assistance, academics must offer up clear ideas about the operational content of the concept of sustainable development. There is an attempt in this regard. The first three chapters provide the "theoretical" context for

the empirical (descriptive) chapters that follow, and it is in these three chapters that the authors attempt a coherent treatment of the idea of sustainable development. Chapter 1 discusses "Sustainable Development: Ecology and Economic Progress." Chapter 2 is titled "Discounting the Future," and chapter 3 is concerned with "Economic Appraisal and the Natural Environment."

It is in chapter 1 that one hopes for real substantive progress on the concept of sustainable development. Here the authors note that, while the notion of sustainable development is prevalent in development thinking, "little headway appears to have been made in terms of a rigorous definition of the concept. Therefore, not surprisingly, efforts to 'operationalize' sustainable development and to show how it can be integrated into practical decision-making have been few and generally unpersuasive" (p. 1).

The authors start by defining development as a vector of desirable objectives or attributes which a society might seek to achieve or to maximize. Listed here are (a) increases in real income per capita, (b) improvements in health and nutritional status, (c) educational achievement, (d) access to resources, (e) a "fairer" distribution of income, and (f) increases in basic freedoms. Sustainable development is then, according to the authors, a situation in which the development vector does not decrease over time.

After defining sustainable development, an attempt is made to define the necessary conditions for achieving sustainable development. The authors note some confusion between these two aspects and hope to clarify matters by this important distinction. The key necessary condition for sustainable development is then said to be "constancy of the natural capital stock. . . . More strictly, the requirement is for non-negative change in the stock of natural resources and environmental quality. In basic terms, the environment should not be degraded further but improvements would be welcome" (p. 4).

The authors properly note that natural capital can be converted into "man-made capital," and that one feasible goal is to seek a constant level of total capital in an economy. In that way, oil that is extracted can be converted into other forms of capital that will keep on giving long after the oil is exhausted. I find this discussion in chapter 1 very helpful and suggestive. My only complaint is that the authors did not apply their considerable talents to a more substantial and elaborate treatment of the subject. This question is, after all, the very core of what is meant by sustainable development.

The final "conceptual" chapter (3) is concerned with the economic appraisal of projects and programs of relevance for natural resources. Sustainable development is assured, we are told, if the benefit-cost analysis of a constellation of projects (a program) is modified by:

. . . setting a constraint on the depletion and degradation of the stock of natural capital. Essentially,

the economic efficiency objective is modified to mean that all projects yielding net benefits should be undertaken subject to the requirement that environmental damage (i.e. natural capital depletion) should be zero or negative. However, applied at the level of each *project* such a requirement would be stultifying . . . At the *programme* level, however, the interpretation is more interesting. It amounts to saying that netted out across a set of projects (programme), the *sum* of individual damages should be zero or negative. (page 59)

This idea is operationalized by including in any set of projects a shadow project whose purpose is exactly to offset the detrimental effects of the proposed investment portfolio, not at the project level, but so as to hold the natural capital stock constant across all activities in the nation. While an interesting idea, note that it is at odds with the discussion in earlier chapters where it was recognized that the aggregate capital stock, consisting of both natural and man-made assets, is of overarching economic importance. Because this chapter is only three and one-half pages long (albeit with a five-page appendix), one wishes that more time and thought had been devoted to these critical issues.

For it is here that one encounters the difficulty in pondering sustainable development as it relates to natural resources and the environment. Some participants in the discussion will regard natural resources and the environment as meaningful objects in their own right. Others will regard the values which flow from natural resources and the environment as the objects of policy interest. Finally, there are those who will regard all capital—natural and man-made—as mere means to an end; that end being to give rise to income and wealth. The formulation adopted by the authors seems consistent with the second of these formulations. Their formulation ignores the intrinsic values of the natural environment, and it confines relevant economic benefits to those arising from natural resources.

In a sense, this book has two personalities. The first three chapters are suggestive but stand as incomplete if we are to develop an operational concept of sustainable development. I wish the authors had spent much more time here; they are well-qualified to make significant contributions in this regard. Had this more elaborate work been undertaken on the conceptual front, the six descriptive chapters could have been written very differently. One almost gets the impression that the latter chapters existed before the three early conceptual chapters and were then modified to give them a flavor of sustainable development. The concepts in the first three chapters are rarely present in the descriptive chapters, though sustainable development is of course mentioned often enough.

I have little quarrel with what is here. It is what is not here that is troublesome. Pearce, Barbier, and Markandya have much to offer us, and I hope they

do just that in a more substantial undertaking in the very near future.

Daniel W. Bromley
University of Wisconsin

van der Meer, Cornelis L. J., and Saburo Yamada. *Japanese Agriculture, A Comparative Economic Analysis*. London: Routledge, 1990, xvi + 217 pp., \$65.00.

This book is a welcome addition to several recent studies on Japanese agricultural problems. In the preface, the authors point out that Japan's "major problem is the very high prices of agricultural commodities in comparison with international prices." Hence, "through international comparative economic analysis, this study tries to reveal to what extent recent Japanese agriculture has stagnated and to analyze the reason why" (p. xiv).

The method used is total factor productivity analysis. After citing several studies on "productivity performance in modern Japanese agriculture," including the work of Yamada himself, the authors find that "the concepts of output and productivity used in these studies have shortcomings for inter-country comparison of real value added and economic efficiency" (p. 2). The purpose of this volume is then to fill the gap in the literature. "Our study is the first to make a detailed real comparison of total production, current inputs, use of fixed capital and value added in Japan and other countries" (p. 2). The authors summarize the finding of their work as follows. "It reveals that real net value added in Japan's agriculture at US and Dutch prices is negative. Our study also analyses the mechanisms by which this negative outcome has been attained: i.e. the dynamic interaction of over-protection of agriculture and excessive use of resources in this sector" (p. 2).

The book consists of eight chapters, four appendices, eight figures, and seventy-two tables. After a brief introduction, in chapter 2 the authors carefully compare the "growth rates of sectoral labor productivity (gross value added per worker) over the period 1960–85 for eighty-one countries grouped by major region and developing status" (p. 24). It appears that, among the seventeen industrial economies, Japan is the only country which has a growth rate of labor productivity smaller for agriculture than for industry (p. 26). This is the case especially during 1975–85. Using least squares method and correlation, the causes of differences in agricultural labor productivity growth are attributed to the growth of labor productivity in nonagricultural sectors, share of agricultural employment (p. 35), price level for final output (p. 38).

Country comparisons of the levels of labor and land productivities and their growth rates for years 1963, 1975, 1985 are presented in chapter 3. It "identified

stagnation of gross value added per worker in Japanese agriculture in the 1975–85 period, poor performance relative to the predicted level on the basis of international comparison, and a negative effect of the high price level on productivity performance based on the confirmed inverse U-shape hypothesis" (p. 67), which, incidentally, is a sort of backward-bending labor supply curve.

The book then makes an in-depth comparison of agricultural development in Japan and the Netherlands (chap. 4). "A remarkable finding" (p. 11) is that the gap in real agricultural productivity, whether measured in 1975 Japanese prices, or Dutch prices, or international dollars, has increased gradually since 1880 (p. 77), while the gap in land productivity decreased (p. 80). Furthermore, "compared to the corresponding Dutch total factor productivity performance, Japanese agriculture lagged much behind the Netherlands, in particular for the period 1975–85" (p. 89).

The comparison extends to the first half of chapter 5. "The productivity gap is biggest for arable production and smallest for horticulture" (p. 129). The former gap "supports the general belief that land scarcity and small farm-sizes are obstacles for achieving high productivity in Japan" (p. 129). However, these reasons are not enough to explain the gap in horticulture and livestock, which are not very land intensive (p. 129).

Two more countries, Taiwan and the United States, are then added for an in-depth comparison in the second half of chapter 5. The comparison of real labor productivities with Taiwan at different relative prices (p. 117) shows that "Taiwan has taken over the leadership role in productivity in Asian agriculture from Japan" (p. 118). It shows that "Japan's level of agricultural protection is among the highest in the world" (p. 131). This chapter is more on methodology of international comparison than country comparison. The authors compare their findings with other studies, and find that "growth rates at constant national

prices may differ considerably from growth rates at constant international prices" (p. 129).

The reasons of Japan's poor performance in agriculture are analyzed in chapter 7. The authors argue that rapid growth in industry lead to "strong protection for agriculture" (p. 135). The Japanese political structure is such that "the rural votes weigh much heavier than urban votes . . . that the continuously ruling Liberal Democratic Party depends much on rural votes and funding . . ." (p. 139). The concern of food security and weak consumer voices enable the government to maintain continued protection and high prices of agricultural goods.

The book concludes with brief discussions of the future (chap. 7) of Japanese agriculture, and the relevance of Japan's post-war development experience for developing countries (chap. 8).

The data used are mainly from international sources like FAO, APO, ILO, and CBS, and are carefully documented in extensive footnotes and appendices. Although technical terms are also explained in appendices, the book is not easy to read and comprehend. Nontechnical readers may lose the focus of some chapters as the materials tend to be repetitive, fragmentary, and sometimes extraneous to the title of the chapter. The quantitative tools used are elaborate classical economic statistics, correlation, and regression. We may note that, in recent years, there are many papers dealing with the U.S. productivity slowdown in manufacturing. The method used is also total factor productivity analysis. Thus, more econometrics-oriented readers may wonder whether the new approach can be applied to analyze Japan's productivity slowdown in agriculture. Until this new approach is done, either by the authors or by others, current researchers on Japan's agricultural development will undoubtedly find this book one of the most comprehensive and useful references.

**europaean review
of agricultural economics**

Editor: Arie Oskam
Agricultural University
Wageningen, The Netherlands

The **European Review of Agricultural Economics** serves as a forum for discussions about the development of theoretical and applied agricultural economics research in Europe and for stimulating ideas regarding the economic problems of agriculture in Europe and other parts of the world.

The **ERAE** also promotes discussion on national resource use, protection of the environment, marketing of agricultural products and development of rural areas. Throughout, the **ERAE** strives for balanced coverage of all issues in agricultural economics: production economics, operations research and farm management problems, agricultural policy, including farm incomes and farm structure, regional planning and rural development, supply analysis, factor markets, demand analysis and marketing, international trade and development, statistical and econometric methods, etc. Original articles as well as full or abstracted articles which have already appeared in national publications and/or in other languages are included. Shorter features supplement the main contents and ensure that the most recent information available is covered. These features include research notes, book reviews, comments on previously published articles and news items about European activities in the field of agricultural economics such as meetings and conferences.

The **European Review of Agricultural Economics** is published as one volume of four issues per year (approximately 510 pages).

Subscription rates for Volume 18 (1991):

Institutions/libraries	DM 248.00 (plus postage)
Individuals (prepaid only*)	DM 120.80 (includes postage)
Single issues	DM 67.00

Prices in US\$ for subscriptions in North America only:

Institutions/libraries	US\$ 160.00 (plus postage)
Individuals (prepaid only*)	US\$ 55.20 (includes postage)

* Subscriptions for individuals are for personal use only and must be prepaid and ordered directly from the publisher. Prepayment may be made by check or by credit card: MasterCard [Access], EuroCard, Visa, and American Express [AMEX may not be used in North America]. Orders placed for institutions will be invoiced at the institutional rate. The individual rate is not available in the FRG, Switzerland, or Austria.
